Generalized complex geometry

Marco Gualtieri

Abstract

Generalized complex geometry encompasses complex and symplectic geometry as its extremal special cases. We explore the basic properties of this geometry, including its enhanced symmetry group, elliptic deformation theory, relation to Poisson geometry, and local structure theory. We also define and study generalized complex branes, which interpolate between flat bundles on Lagrangian submanifolds and holomorphic bundles on complex submanifolds.

Introduction

Generalized complex geometry arose from the work of Hitchin [18] on geometries defined by stable differential forms of mixed degree. Algebraically, it interpolates between a symplectic form $\omega$ and a complex structure $J$ by viewing each as a complex (or equivalently, symplectic) structure $J$ on the direct sum of the tangent and cotangent bundles $T \oplus T^*$, compatible with the natural split-signature metric which exists on this bundle. Remarkably, there is an integrability condition on such generalized complex structures which specializes to the closure of the symplectic form on one hand, and the vanishing of the Nijenhuis tensor of $J$ on the other.

This is simply that $J$ must be integrable with respect to the Courant bracket, an extension of the Lie bracket of vector fields to smooth sections of $T \oplus T^*$ which was introduced by Courant and Weinstein [11],[12] in their study of Dirac structures. Dirac structures interpolate between Poisson bivector fields and closed 2-forms; in this sense, generalized complex geometry is a complex analogue of Dirac geometry.

We begin, in parts 1 and 2, with a study of the natural split-signature orthogonal structure on $T \oplus T^*$ and its associated spin bundle $\wedge \cdot T^*$, the bundle of differential forms. Viewing forms as spinors then leads to a natural definition of the Courant bracket, and we study two remarkable properties of this bracket: first, its symmetry group is an extension of the group of diffeomorphisms by the abelian group of closed 2-forms (B-field transformations), and second, it can be "twisted" by a real closed 3-form $H$. We describe what this means in the language of gerbes and exact Courant algebroids. We also provide a brief review of Dirac geometry and introduce the notion of tensor product of Dirac structures, obtained independently by Alekseev-Bursztyn-Meinrenken in [3].

In part 3, we treat the basic properties of generalized complex structures. We show that any generalized complex manifold admits almost complex structures, and has two natural sets of Chern classes $c^\pm_k$. We also show that a generalized complex structure is determined by a complex pure spinor line subbundle $K \subset \wedge \cdot T^* \otimes \mathbb{C}$, the canonical bundle, which can be seen as the minimal degree component of a natural grading of the Courant bundle, and we study two remarkable properties of this bracket: first, its symmetry group is an extension of the group of diffeomorphisms by the abelian group of closed 2-forms (B-field transformations), and second, it can be "twisted" by a real closed 3-form $H$. We describe what this means in the language of gerbes and exact Courant algebroids. We also provide a brief review of Dirac geometry and introduce the notion of tensor product of Dirac structures, obtained independently by Alekseev-Bursztyn-Meinrenken in [3].

In part 4, we prove a local structure theorem for generalized complex manifolds, analogous to the Darboux theorem in symplectic geometry and the Newlander-Nirenberg theorem in complex geometry. We show that near any regular point for the Poisson structure $P$, the generalized complex manifold is equivalent, via a diffeomorphism and a B-field transformation, to a product of a complex space of dimension $k$ (called the type) with a symplectic space. Finally, we provide an example of a generalized complex manifold whose type is constant outside of a submanifold, along which it jumps to a higher value.

In part 5, we develop the deformation theory of generalized complex manifolds. It is governed by a differential Gerstenhaber algebra $(C^\infty(\wedge^k L^*), d_L, [\cdot,\cdot])$ constructed from the $+i$-eigenbundle $L$ of $J$. This differential complex is elliptic, and therefore has finite-dimensional cohomology groups $H^k(M, L)$ over a compact manifold $M$. Integrable deformations correspond to sections $\epsilon \in C^\infty(\wedge^2 L^*)$ satisfying the Maurer-Cartan equation

$$d_L \epsilon + \frac{1}{2} [\epsilon, \epsilon] = 0.$$  

Similarly to the case of deformations of complex structure, there is an analytic obstruction map $\Phi : H^2(M, L) \to H^3(M, L)$, and if this vanishes then there is a locally complete family of deformations parametrized by an open set in $H^2(M, L)$. In the case that we are deforming
a complex structure, this cohomology group turns out to be

\[ H^0(M, \Lambda^2 T) \oplus H^1(M, T) \oplus H^2(M, O). \]

This is familiar as the “extended deformation space” of Barannikov and Kontsevich [4], for which a geometrical interpretation has been sought for some time. Here it appears naturally as the deformation space of a complex structure in the generalized setting.

Finally, in part 6, we introduce generalized complex branes, which are vector bundles supported on submanifolds for which the pullback of the ambient gerbe is trivializable, together with a natural requirement of compatibility with the generalized complex structure. The definition is similar to that of a D-brane in physics; indeed, we show that for a usual symplectic manifold, generalized complex branes consist not only of flat vector bundles supported on Lagrangian submanifolds, but also certain bundles over a class of coisotropic submanifolds equipped with a holomorphic symplectic structure transverse to their characteristic foliation. These are precisely the co-isotropic A-branes discovered by Kapustin and Orlov [22].

This article is largely based upon the author’s doctoral thesis [17], supported by the Rhodes Trust. Thanks are due especially to Nigel Hitchin for his guidance and insight. Many thanks as well to Henrique Bursztyn, Gil Cavalcanti, Jacques Hurtubise, Anton Kapustin, and Alan Weinstein for helpful conversations.

1 Linear geometry of \( T \oplus T^* \)

Let \( V \) be a real vector space of dimension \( m \), and let \( V^* \) be its dual space. Then \( V \oplus V^* \) is endowed with a natural symmetric bilinear form

\[ \langle X + \xi, Y + \eta \rangle = \frac{1}{2}(\xi(Y) + \eta(X)). \]

This non-degenerate inner product has signature \((m, m)\) and therefore has symmetry group \( O(V \oplus V^*) \cong O(m, m) \), a non-compact orthogonal group. In addition, \( V \oplus V^* \) has a canonical orientation, since \( \det(V \oplus V^*) = \det V \otimes \det V^* = \mathbb{R} \).

1.1 Symmetries of \( V \oplus V^* \)

The Lie algebra of the special orthogonal group \( SO(V \oplus V^*) \) is defined as usual:

\[ \mathfrak{so}(V \oplus V^*) = \{ R \mid \langle Tx, y \rangle + \langle x, Ty \rangle = 0 \ \forall \ x, y \in V \oplus V^* \} . \]

Using the splitting \( V \oplus V^* \) we can decompose as follows:

\[ T = \begin{pmatrix} A & \beta \\ B & -A^* \end{pmatrix}, \tag{1.1} \]

where \( A \in \text{End}(V) \), \( B : V \to V^* \), \( \beta : V^* \to V \), and where \( B \) and \( \beta \) are skew, i.e. \( B^* = -B \) and \( \beta^* = -\beta \). Therefore we may view \( B \) as a 2-form in \( \Lambda^2 V^* \) via \( B(X) = i_X B \) and similarly we may regard \( \beta \) as an element of \( \Lambda^2 V \), i.e. a bivector. This corresponds to the observation that \( \mathfrak{so}(V \oplus V^*) = \Lambda^2(V \oplus V^*) = \text{End}(V) \oplus \Lambda^2 V^* \oplus \Lambda^2 V \).

By exponentiation, we obtain certain important orthogonal symmetries of \( T \oplus T^* \) in the identity component of \( SO(V \oplus V^*) \).

**Example 1.1** (B-transform). First let \( B \) be as above, and consider

\[ \exp(B) = \begin{pmatrix} 1 \\ B & 1 \end{pmatrix}, \tag{1.2} \]

an orthogonal transformation sending \( X + \xi \mapsto X + \xi + i_X B \). It is useful to think of \( \exp(B) \) a shear transformation, which fixes projections to \( V \) and acts by shearing in the \( V^* \) direction.
Example 1.2 (β-transform). Similarly, let $\beta$ be as above, and consider

$$\exp(\beta) = \begin{pmatrix} 1 & \beta \\ \beta & 1 \end{pmatrix},$$

an orthogonal transformation sending $X + \xi \mapsto X + \xi + i\xi \beta$. Again, it is useful to think of $\exp(\beta)$ a shear transformation, which fixes projections to $T^*$ and acts by shearing in the $T$ direction.

Example 1.3. If we choose $A \in \text{End}(V)$ as above, then since

$$\exp(A) = \left( \exp A \cdot (\exp A^*)^{-1} \right),$$

we have a distinguished embedding of $GL^+(V)$ into the identity component of $SO(V \oplus V^*)$.

1.2 Maximal isotropic subspaces

A subspace $L \subset V \oplus V^*$ is isotropic when $\langle x, y \rangle = 0$ for all $x, y \in L$. Since we are in signature $(m, m)$, the maximal dimension of such a subspace is $m$, and if this is the case, $L$ is called maximal isotropic. Maximal isotropic subspaces of $V \oplus V^*$ are also called linear Dirac structures (see [11]). Note that $V$ and $V^*$ are examples of maximal isotropics. The space of maximal isotropics has two connected components, and elements of these are said to have even or odd parity, depending on whether they share their connected component with $V$ or not, respectively. This situation becomes more transparent after studying the following two examples.

Example 1.4. Let $\Delta \subset V$ be any subspace. Then the subspace

$$\Delta \oplus \text{Ann}(\Delta) \subset V \oplus V^*,$$

where Ann(Δ) is the annihilator of Δ in $V^*$, is maximally isotropic.

Example 1.5. Let $i : \Delta \hookrightarrow V$ be a subspace inclusion, and let $\varepsilon \in \wedge^2 \Delta^*$. Then the subspace

$$L(\Delta, \varepsilon) = \{X + \xi \in \Delta \oplus V^* : i^*\xi = iX\varepsilon\} \subset V \oplus V^*$$

is an extension of the form

$$0 \longrightarrow \text{Ann}(\Delta) \longrightarrow L(\Delta, \varepsilon) \longrightarrow \Delta \longrightarrow 0,$$

and satisfies $\langle X + \xi, Y + \eta \rangle = \frac{1}{2}(\varepsilon(Y, X) + \varepsilon(X, Y)) = 0$ for all $X + \xi, Y + \eta \in L(\Delta, \varepsilon)$, showing that $L(\Delta, \varepsilon)$ is a maximal isotropic subspace.

Note that the second example specializes to the first by taking $\varepsilon = 0$. Furthermore note that $L(V, 0) = V$ and $L(\{0\}, 0) = V^*$. It is not difficult to see that every maximal isotropic is of this form:

Proposition 1.6. Every maximal isotropic in $V \oplus V^*$ is of the form $L(\Delta, \varepsilon)$.

Proof. Let $L$ be a maximal isotropic and define $\Delta = \pi_V L$, where $\pi_V$ is the canonical projection $V \oplus V^* \longrightarrow V$. Then since $L$ is maximal isotropic, $L \cap V^* = \text{Ann}(\Delta)$. Finally note that $\Delta^* = V^*/\text{Ann}(\Delta)$, and define $\varepsilon : \Delta \rightarrow \Delta^*$ via $\varepsilon : x \mapsto \pi_V \cdot (\pi_V^{-1}(x) \cap L) \in V^*/\text{Ann}(\Delta)$. Then $L = L(\Delta, \varepsilon)$. \(\blacksquare\)

The integer $k = \dim \text{Ann}(\Delta) = m - \dim \pi_V(L)$ is a useful invariant associated to a maximal isotropic in $V \oplus V^*$, and determines the parity as we now explain.
Definition 1.7. The type of a maximal isotropic \( L \subset V \oplus V^* \) is the codimension \( k \) of its projection onto \( V \).

Since a \( B \)-transform preserves projections to \( V \), it does not affect \( \Delta \):

\[
\exp B(L(\Delta, \varepsilon)) = L(\Delta, \varepsilon + i^* B),
\]

where \( i : \Delta \hookrightarrow V \) is the inclusion. Hence \( B \)-transforms do not change the type of the maximal isotropic. In fact, we see that by choosing \( B \) and \( \Delta \) accordingly, we can obtain any maximal isotropic as a \( B \)-transform of \( L(\Delta, 0) \).

On the other hand, \( \beta \)-transforms do modify projections to \( V \), and therefore may change the dimension of \( \Delta \). To see how this occurs, we express the maximal isotropic as a generalized graph from \( V^* \rightarrow V \), i.e. define \( F = \pi_V L \) and \( \gamma \in \wedge^2 F^* \) given by \( \gamma(y) = \pi_V(\pi_V^{-1}(y) \cap L) \) modulo \( \text{Ann}(F) \). As before, define

\[
L(F, \gamma) = \{ X + \xi \in V \oplus F : j^* X = i \xi \gamma \},
\]

where \( j : F \hookrightarrow V^* \) is the inclusion. Now, the projection \( \Delta = \pi_V L(F, \gamma) \) always contains \( L \cap V = \text{Ann}(F) \), and if we take the quotient of \( \Delta \) by this subspace we obtain the image of \( \gamma \) in \( F^* = V/\text{Ann}(F) \):

\[
\frac{\Delta}{L \cap V} = \frac{\Delta}{\text{Ann}(F)} = \text{Im}(\gamma).
\]

Therefore, we obtain the dimension of \( \Delta \) as a function of \( \gamma \):

\[
\dim \Delta = \dim L \cap V + \text{rk } \gamma.
\]

Because \( \gamma \) is a skew form, its rank is even. A \( \beta \)-transform sends \( \gamma \mapsto \gamma + j^* \beta \), which also has even rank, and therefore we see that a \( \beta \)-transform, which is in the identity component of \( SO(V \oplus V^*) \), can be used to change the dimension of \( \Delta \), and hence the type of \( L(\Delta, \varepsilon) \), by an even number, yielding the following result.

Proposition 1.8. The space of maximal isotropics in \( V \oplus V^* \) has two connected components, distinguished by the parity of the type; maximal isotropics have even parity if and only if they share a connected component with \( V \).

1.3 Spinors for \( V \oplus V^* \): exterior forms

Let \( CL(V \oplus V^*) \) be the Clifford algebra defined by the relation

\[
v^2 = \langle v, v \rangle, \quad \forall v \in V \oplus V^*,
\]

(1.6)

The Clifford algebra has a natural representation on \( S = \wedge^* V^* \) given by

\[
(X + \xi) \cdot \varphi = i_X \varphi + \xi \wedge \varphi,
\]

(1.7)

where \( X + \xi \in V \oplus V^* \) and \( \varphi \in \wedge^* V^* \). We verify that this defines an algebra representation:

\[
(X + \xi)^2 \cdot \varphi = i_X (i_X \varphi + \xi \wedge \varphi) + \xi \wedge (i_X \varphi + \xi \wedge \varphi)
= (i_X \xi) \varphi
= \langle X + \xi, X + \xi \rangle \varphi,
\]

as required. This representation is the standard spin representation, so that \( CL(V \oplus V^*) = \text{End}(\wedge^* V^*) \). Since in signature \((m, m)\) the volume element \( \omega \) of a Clifford algebra satisfies \( \omega^2 = 1 \), the spin representation decomposes into the \( \pm 1 \) eigenspaces of \( \omega \) (the positive and negative helicity spinors):

\[
S = S^+ \oplus S^-,
\]

5
corresponding to the decomposition
\[ \wedge^\bullet V^* = \wedge^s V^* \oplus \wedge^d V^* \]
according to parity. While the splitting \( S = S^+ \oplus S^- \) is not preserved by the whole Clifford algebra, \( S^\pm \) are irreducible representations of the spin group, which sits in the Clifford algebra as
\[ \text{Spin}(V \oplus V^*) = \{ v_1 \cdots v_r : v_i \in V \oplus V^*, \langle v_i, v_i \rangle = \pm 1 \text{ and } r \text{ even} \}, \]
and which is a double cover of \( SO(V \oplus V^*) \) via the homomorphism
\[ \rho : \text{Spin}(V \oplus V^*) \longrightarrow SO(V \oplus V^*) \]
\[ \rho(x)(v) = x vx^{-1}, \quad x \in \text{Spin}(V \oplus V^*), \quad v \in V \oplus V^*. \quad (1.8) \]
We now describe the action of \( \mathfrak{so}(V \oplus V^*) \) in the spin representation. Recall that \( \mathfrak{so}(V \oplus V^*) = \wedge^2(V \oplus V^*) \) sits naturally inside the Clifford algebra, and that the derivative of \( \rho \), given by
\[ d\rho_x(v) = xv - vx = [x, v], \quad x \in \mathfrak{so}(V \oplus V^*), \quad v \in V \oplus V^*, \]
defines the usual representation of \( \mathfrak{so}(V \oplus V^*) \) on \( V \oplus V^* \). In the following we take \( \{ e_i \} \) to be a basis for \( V \) and \( \{ e^i \} \) the dual basis.

**Example 1.9** (B-transform). A 2-form \( B = \frac{1}{2} B_{ij} e^i \wedge e^j \), \( B_{ij} = -B_{ji} \), has image in the Clifford algebra given by \( \frac{1}{2} B_{ij} e^i e^j \). Its spinorial action on a form \( \varphi \in \wedge^\bullet V^* \) is
\[ B \cdot \varphi = \frac{1}{2} B_{ij} e^i \wedge (e^i \wedge \varphi) = -B \wedge \varphi. \]
Exponentiating, we obtain
\[ e^{-B} \varphi = (1 - B + \frac{1}{2} B \wedge B + \cdots) \wedge \varphi. \quad (1.9) \]

**Example 1.10** (β-transform). A bivector \( \beta = \frac{1}{2} \beta^{ij} e_i \wedge e_j \), \( \beta^{ij} = -\beta^{ji} \), has image in the Clifford algebra given by \( \frac{1}{2} \beta^{ij} e^i e^j \). Its spinorial action on a form \( \varphi \) is
\[ \beta \cdot \varphi = \frac{1}{2} \beta^{ij} i_{e_j} (i_{e_i} \varphi) = i_\beta \varphi. \]
Exponentiating, we obtain
\[ e^{i_\beta} \varphi = (1 + i_\beta + \frac{1}{2} i_\beta^2 + \cdots) \varphi. \quad (1.10) \]

**Example 1.11** (GL^+(V) action). An endomorphism \( A = A^i_j e^j \otimes e_j \) has image in the Clifford algebra given by \( \frac{1}{2} A^i_j (e^j e^i - e^i e_j) \), and has spinorial action
\[ A \cdot \varphi = \frac{1}{2} A^i_j (i_{e_j} (e^i \wedge \varphi) - e^i \wedge i_{e_j} \varphi) = \frac{1}{2} A^i_j \delta_j^i \varphi - A^i_j e^i \wedge i_{e_j} \varphi = -A^* \varphi + \frac{1}{2} \text{Tr}(A) \varphi, \]
where \( \varphi \mapsto -A^* \varphi = -A^i_j e^i \otimes i_{e_j} \varphi \) is the usual action of \( \text{End}(V) \) on \( \wedge^\bullet V^* \). Hence, by exponentiation, the spinorial action of \( \text{GL}^+(V) \) on \( \wedge^\bullet V^* \) is by
\[ g \cdot \varphi = \sqrt{\det g(g^*)^{-1}} \varphi, \]
i.e. as a \( \text{GL}^+(V) \) representation the spinor representation decomposes as
\[ S = \wedge^\bullet V^* \otimes (\text{det } V)^{1/2}. \quad (1.11) \]
In fact, as we shall see in the following sections, tensoring with the half densities as in \( (1.11) \) renders \( S \) independent of polarization, i.e. if \( N, N' \) are maximal isotropic subspaces such that \( V \oplus V^* = N \oplus N' \), then the inner product gives an identification \( N' = N^* \), and one obtains a canonical isomorphism \( \wedge^\bullet V^* \otimes (\text{det } V)^{1/2} = \wedge^\bullet N^* \otimes (\text{det } N)^{1/2} \).
1.4 The Mukai pairing

There is an invariant bilinear form on spinors, which we now describe, following the treatment of Chevalley [10]. For $V \oplus V^*$ this bilinear form coincides with the Mukai pairing of forms [31].

Since we have the splitting $V \oplus V^*$ into maximal isotropics, the exterior algebras $\wedge^* V$ and $\wedge^* V^*$ are subalgebras of $CL(V \oplus V^*)$. In particular, $\det V$ is a distinguished line inside $CL(V \oplus V^*)$, and it generates a left ideal with the property that upon choosing a generator $f \in \det V$, every element of the ideal has a unique representation as $sf$, $s \in \wedge^* V^*$. This defines an action of the Clifford algebra on $\wedge^* V^*$ by

$$(x \cdot s)f = xsf \quad \forall x \in CL(V \oplus V^*),$$

which is the same action as that defined by (1.7).

Let $x \mapsto x^\top$ denote the main anti Automorphism of the Clifford algebra, i.e. that determined by the tensor map $v_1 \otimes \cdots \otimes v_k \mapsto v_k \otimes \cdots \otimes v_1$. Now let $s,t \in \wedge^* V^*$ and consider the Mukai pairing $(\cdot,\cdot): \wedge^* V^* \otimes \wedge^* V^* \rightarrow \det V^*$ given by

$$(s,t) = [s^\top \wedge t]_m,$$

where $[\cdot]_m$ indicates projection to the component of degree $m = \dim V$. We can express $(\cdot,\cdot)$ in the following way, using any generator $f \in \det V$:

$$(i_f(s,t))f = (i_f(s^\top \wedge t))f = (f^\top \cdot (s^\top t))f = (sf)^\top tf. \quad (1.12)$$

From this description, we see immediately that

$$(x \cdot s,t) = (s,x^\top \cdot t), \quad \forall x \in CL(V \oplus V^*). \quad (1.13)$$

In particular $(g \cdot s,g \cdot t) = \pm (s,t)$ for any $g \in \text{Spin}(V \oplus V^*)$, yielding the following result.

**Proposition 1.12.** The Mukai pairing is invariant under the identity component of Spin:

$$(g \cdot s,g \cdot t) = (s,t) \quad \forall g \in \text{Spin}_0(V \oplus V^*).$$

**Therefore it determines a Spin$_0$-invariant bilinear form on $S = \wedge^* V^* \otimes (\det V)^{1/2}$.**

For example, we have $(\exp B \cdot s,\exp B \cdot s) = (s,t)$, for any $B \in \wedge^2 V^*$. The pairing is non-degenerate, and is symmetric or skew-symmetric depending on the dimension of $V$, since

$$(s,t) = (-1)^{m(m-1)/2}(t,s).$$

We also see from degree considerations that for $m$ even, $(S^+,S^-) = 0$.

**Example 1.13.** Suppose $V$ is 4-dimensional; then the Mukai pairing is symmetric, and the even spinors are orthogonal to the odd spinors. The inner product of even spinors $\rho = \rho_0 + \rho_2 + \rho_4$ and $\sigma = \sigma_0 + \sigma_2 + \sigma_4$ is given by

$$(\rho,\sigma) = [(\rho_0 - \rho_2 + \rho_4) \wedge (\sigma_0 + \sigma_2 + \sigma_4)]_4$$

$$= \rho_0 \wedge \sigma_4 - \rho_2 \wedge \sigma_2 + \rho_4 \wedge \sigma_0.$$

The inner product of odd spinors $\rho = \rho_1 + \rho_3$ and $\sigma = \sigma_1 + \sigma_3$ is given by

$$(\rho,\sigma) = [(\rho_1 - \rho_3) \wedge (\sigma_1 + \sigma_3)]_4$$

$$= \rho_1 \wedge \sigma_3 - \rho_3 \wedge \sigma_1.$$
1.5 Pure spinors and polarizations

Let $\varphi \in \wedge^* V^*$ be a nonzero spinor. We define its null space $L_\varphi < V \oplus V^*$, as follows:

$$L_\varphi = \{ v \in V \oplus V^* : v \cdot \varphi = 0 \},$$

and it is clear from (1.8) that $L_\varphi$ depends equivariantly on $\varphi$, i.e.:

$$L_{g \varphi} = \rho(g)L_\varphi \quad \forall g \in \text{Spin}(V \oplus V^*).$$

The key property of null spaces is that they are isotropic: if $v, w \in L_\varphi$, we have

$$(v, w)\varphi = \frac{1}{2}(vw + vw) \cdot \varphi = 0.$$  

**Definition 1.14.** A spinor $\varphi$ is called pure when $L_\varphi$ is maximal isotropic.

Every maximal isotropic subspace $L \subset V \oplus V^*$ is represented by a unique line $K_L \subset \wedge^* V^*$ of pure spinors, as we now describe. As we saw in section 1.2, any maximal isotropic $L(\Delta, \epsilon)$ may be expressed as the $B$-transform of $L(\Delta, 0)$ for $B$ chosen such that $i^*B = -\epsilon$. The pure spinor line with null space $L(\Delta, 0) = \Delta + \text{Ann}(\Delta)$ is precisely $\det(\text{Ann}(\Delta)) \subset \wedge^k V^*$, for $k$ the codimension of $\Delta \subset V$. Hence we obtain the following result.

**Proposition 1.15** ([10], III.1.9.). Let $L(\Delta, \epsilon) \subset V \oplus V^*$ be maximal isotropic, let $(\theta_1, \ldots, \theta_k)$ be a basis for $\text{Ann}(\Delta)$, and let $B \in \wedge^2 V^*$ be a 2-form such that $i^*B = -\epsilon$, where $i : \Delta \rightarrow V$ is the inclusion. Then the pure spinor line $K_L$ representing $L(\Delta, \epsilon)$ is generated by

$$\varphi = \exp(B)\theta_1 \wedge \cdots \wedge \theta_k.$$  

(1.14)

Note that $\varphi$ is of even or odd degree according as $L$ is of even or odd parity.

$L$ may also be described as a generalized graph on $V^*$ via (1.5), expressing it as a $\beta$-transform of $L(F, 0)$, which has associated pure spinor line $\det(L \cap V)$. As a result we obtain the following complement to Proposition 1.15.

**Proposition 1.16.** Given a subspace inclusion $i : \Delta \rightarrow V$ and a 2-form $B \in \wedge^2 V^*$, there exists a bivector $\beta \in \wedge^2 V$, such that

$$e^B \det(\text{Ann}(\Delta)) = e^\beta \det(\text{Ann}(L \cap V))$$

is an equality of pure spinor lines, where $L = L(\Delta, -i^*B)$. Note that the image of $\beta$ in $\wedge^2(V/(L \cap V))$ is unique.

The pure spinor line $K_L$ determined by $L$ forms the beginning of an induced filtration on the spinors, as we now describe. Recall that the Clifford algebra is a $\mathbb{Z}/2\mathbb{Z}$-graded, $\mathbb{Z}$-filtered algebra with

$$CL(V \oplus V^*) = CL^{2m} \supset CL^{2m-1} \supset \cdots \supset CL^0 = \mathbb{R}$$

where $CL^k$ is spanned by products of $\leq k$ generators. By the Clifford action on $K_L$, we obtain a filtration of the spinors:

$$K_L = F_0 \subset F_1 \subset \cdots \subset F_m = S$$  

(1.15)

where $F_k$ is defined as $CL^k \cdot K_L$. Note that $CL^k \cdot K_L = CL^{m-k} \cdot K_L$ for $k > m$ since $L$ annihilates $K_L$. Also, using the inner product, we have the canonical isomorphism $L^* = (V \oplus V^*)/L$, and so $F_k/F_{k-1}$ is isomorphic to $\wedge^k L^* \otimes K_L$.

The filtration just described becomes a grading when a maximal isotropic $L' \subset V \oplus V^*$ complementary to $L$ is chosen. Then we obtain a $\mathbb{Z}$-grading on $S = \wedge^* V^*$ of the form (for $\dim V$ even, i.e. $m = 2n$)

$$S = U^{-n} \oplus \cdots \oplus U^n,$$  

(1.16)
where \( U^{-n} = K_L \) and \( U^k = (\Lambda^{k+n}L') \cdot K_L \), using the inclusion as a subalgebra \( \Lambda^k L' \supset CL(V \oplus V^*) \). Using the inner product to identify \( L' = L^* \), we obtain the natural isomorphism \( U^k = \Lambda^{k+n}L^* \otimes K_L \) and, summing over \( k \),

\[
\Lambda^* V^* = \Lambda^* L^* \otimes K_L. \tag{1.17}
\]

The line \( U^n = \text{det } L' \cdot U^{-n} \) is the pure spinor line determining \( L' \) and since \( L \cap L' = \{0\} \), the Mukai pairing gives an isomorphism

\[
U^{-n} \otimes U^n = \text{det } V^*, \tag{1.18}
\]

as can be seen from the nondegenerate pairing between \( \Lambda^0 V^* \) and \( \text{det } V^* \) and the Spin-invariance of the Mukai pairing. This is an example of how the Mukai pairing determines the intersection properties of maximal isotropics, and it can be phrased as follows:

**Proposition 1.17** (**[10]**, III.2.4.). Maximal isotropics \( L, L' \) satisfy \( L \cap L' = \{0\} \) if and only if their pure spinor representatives \( \varphi, \varphi' \) satisfy \( \langle \varphi, \varphi' \rangle \neq 0 \).

Furthermore, applying (1.13), we see that the Mukai pairing provides a nondegenerate pairing for all \( k \):

\[
U^{-k} \otimes U^k \rightarrow \text{det } V^*. \]

Finally, rewriting (1.18), we have the isomorphism \( K_L \otimes \text{det } L^* \otimes K_L = \text{det } V^* \), which, combined with (1.17), yields the canonical isomorphism

\[
\Lambda^* V^* \otimes (\text{det } V)^{1/2} = \Lambda^* L^* \otimes (\text{det } L)^{1/2},
\]

showing that tensoring with the half densities renders \( S \) independent of polarization.

### 1.6 The spin bundle for \( T \oplus T^* \)

Consider the direct sum of the tangent and cotangent bundles \( T \oplus T^* \) of a real \( m \)-dimensional smooth manifold \( M \). This bundle is endowed with the same canonical bilinear form and orientation we described on \( V \oplus V^* \). Therefore, while \( T \oplus T^* \) is associated to a \( GL(m) \) principal bundle, we may view it as having natural structure group \( SO(m, m) \).

It is well-known that an oriented bundle with Euclidean structure group \( SO(n) \) admits spin structure if and only if the second Stiefel-Whitney class vanishes, i.e. \( w_2(E) = 0 \). For oriented bundles with metrics of indefinite signature, we find the appropriate generalization in [23], which we now summarize.

If an orientable bundle \( E \) has structure group \( SO(p, q) \), we can always reduce the structure group to its maximal compact subgroup \( S(O(p) \times O(q)) \). This reduction is equivalent to the choice of a maximal positive definite subbundle \( C^+ < E \), which allows us to write \( E \) as the direct sum \( E = C^+ \oplus C^- \), where \( C^- = (C^+)\perp \) is negative definite.

**Proposition 1.18** (**[23]**, 1.1.26). The \( SO(p, q) \) bundle \( E \) admits \( \text{Spin}(p, q) \) structure if and only if \( w_2(C^+) = w_2(C^-) \).

In the special case of \( T \oplus T^* \), which has signature \((m, m)\), the positive and negative definite bundles \( C^\pm \) project isomorphically via \( \pi_T : T \oplus T^* \rightarrow T \) onto the tangent bundle. Hence the condition \( w_2(C^+) = w_2(C^-) \) is always satisfied for \( T \oplus T^* \), yielding the following result.

**Proposition 1.19.** The \( SO(m, m) \) bundle \( T \oplus T^* \) always admits \( \text{Spin}(m, m) \) structure.

By the action defined in (1.7), the differential forms \( \Lambda^* T^* \) are a Clifford module for \( T \oplus T^* \); indeed, for an orientable manifold, we see immediately from the decomposition (1.11) of the spin representation under \( GL^+(m) \) that there is a natural choice of spin bundle, namely

\[
S = \Lambda^* T^* \otimes (\text{det } T)^{1/2}.
\]
The Mukai pairing may then either be viewed as a nondegenerate pairing

\[ \wedge^* T^* \otimes \wedge^* T^* \longrightarrow \det T^* , \]

or as a bilinear form on the spinors \( S \). In the rest of the paper we will make frequent use of the correspondence between maximal isotropics in \( T \oplus T^* \) and pure spinor lines in \( \wedge^* T^* \) to describe structures on \( T \oplus T^* \) in terms of differential forms.

## 2 The Courant bracket

The Courant bracket, introduced in [11], [12], is an extension of the Lie bracket of vector fields to smooth sections of \( T \oplus T^* \). It differs from the Lie bracket in certain important respects. Firstly, its skew-symmetrization does not satisfy the Jacobi identity; as shown in [34] it defines instead a Lie algebra up to homotopy. Secondly, it has an extended symmetry group; besides the diffeomorphism symmetry it shares with the Lie bracket, it admits B-field gauge transformations. Finally, as shown in [35], the bracket may be ‘twisted’ by a closed 3-form \( H \), and so may be viewed as naturally associated to an \( S^1 \)-gerbe.

Like the Lie bracket, the Courant bracket may be defined as a derived bracket; we describe this following the treatment in [24]. We also present, following [33], certain characteristic properties of the Courant bracket as formalized by [28] in the notion of Courant algebroid, a generalization of Lie algebroid.

### 2.1 Derived brackets

The interior product of vector fields \( X \mapsto i_X \) defines an effective action of vector fields on differential forms by derivations of degree \(-1\). Taking supercommutator with the exterior derivative, we obtain a derivation of degree 0, the Lie derivative:

\[ \mathcal{L}_X = [d, i_X] = di_X + i_X d. \]

Taking commutator with another interior product, we obtain an expression for the Lie bracket:

\[ i_{[X,Y]} = [\mathcal{L}_X , i_Y]. \]

In this sense, the Lie bracket on vector fields is ‘derived’ from the Lie algebra of endomorphisms of \( \Omega^\bullet(M) \). Using the spinorial action (1.7) of \( T \oplus T^* \) on forms, we may define the Courant bracket of sections \( e_i \in C^\infty(T \oplus T^*) \) in the same way:

\[ [e_1, e_2] \cdot \varphi = [(d, e_1], [e_2, \varphi] \ orall \varphi \in \Omega^\bullet(M). \] (2.1)

Although this bracket is not skew-symmetric, it follows from the fact that \( d^2 = 0 \) that the following Jacobi identity holds:

\[ [[e_1, e_2], e_3] = [e_1, [e_2, e_3]] - [e_2, [e_1, e_3]]. \] (2.2)

As observed in [35], one may replace the exterior derivative in (2.1) by the twisted operator \( d_H \varphi = d\varphi + H \wedge \varphi \) for a real 3-form \( H \in \Omega^3(M) \). The resulting derived bracket then satisfies

\[ [[e_1, e_2], e_3] = [e_1, [e_2, e_3]] - [e_2, [e_1, e_3]] + i_{\pi e_3} i_{\pi e_2} i_{\pi e_1} dH, \]

where \( \pi : T \oplus T^* \longrightarrow T \) is the first projection. When the last term vanishes, the bracket is called a Courant bracket.
Definition 2.1. Let $e_1, e_2 \in C^\infty(T \oplus T^*)$. Then their $H$-twisted Courant bracket $[e_1, e_2]_H \in C^\infty(T \oplus T^*)$ is defined by the expression

$$[e_1, e_2]_H \cdot \varphi = [[d_H, e_1], e_2] \varphi \quad \forall \varphi \in \Omega^*(M),$$

where $d_H \varphi = d \varphi + H \wedge \varphi$ for $H$ a real closed 3-form.

Expanding this expression for $e_1 = X + \xi$ and $e_2 = Y + \eta$, we obtain

$$[X + \xi, Y + \eta]_H = [X, Y] + L_X \eta - i_Y d\xi + i_X i_Y H. \quad (2.3)$$

The Courant bracket, for any closed 3-form $H$, satisfies the following conditions:

1. $[e_1, [e_2, e_3]] = [[e_1, e_2], e_3] + [e_2, [e_1, e_3]]$, C1
2. $\pi([e_1, e_2]) = [\pi(e_1), \pi(e_2)]$, C2
3. $[e_1, f e_2] = f[e_1, e_2] + (\pi(e_1)f)e_2$, $f \in C^\infty(M)$, C3
4. $\pi(e_1)\langle e_2, e_3 \rangle = \langle [e_1, e_2], e_3 \rangle + \langle e_2, [e_1, e_3] \rangle$, C4
5. $[e_1, e_1] = \pi^* d(e_1, e_1)$, C5

In [28], these properties were promoted to axioms defining the notion of Courant algebroid, which is a real vector bundle $E$ equipped with a bracket $\langle \cdot, \cdot \rangle$, nondegenerate inner product $\langle \cdot, \cdot \rangle$, and bundle map $\pi : E \to T$ (called the anchor) satisfying the conditions C1–C5 above.

Note that if the bracket were skew-symmetric, then axioms C1–C3 would define the notion of Lie algebroid; axiom C5 indicates that the failure to be a Lie algebroid is measured by the inner product, which itself is invariant under the adjoint action by axiom C4).

The Courant algebroid structure on $T \oplus T^*$ has surjective anchor with isotropic kernel given by $T^*$; such Courant algebroids are called exact.

Definition 2.2. A Courant algebroid $E$ is exact when the following sequence is exact:

$$0 \to T^* \xrightarrow{\pi^*} E \xrightarrow{\pi} T \to 0, \quad (2.4)$$

where $E$ is identified with $E^*$ using the inner product.

Exactness at the middle place forces $\pi^*(T^*)$ to be isotropic and therefore the inner product on $E$ must be of split signature. It is then always possible to choose an isotropic splitting $s : T \to E$ for $\pi$, yielding an isomorphism $E \cong T \oplus T^*$ taking the Courant bracket to that given by [23], where $H$ is the curvature of the splitting, i.e.

$$i_X i_Y H = s^* [s(X), s(Y)], \quad X, Y \in T. \quad (2.5)$$

Isotropic splittings of [2.4] are acted on transitively by the 2-forms $B \in \Omega^2(M)$ via transformations of the form $X + \xi \mapsto X + \xi + i_X B$, or more invariantly,

$$e \mapsto e + \pi^* i_{\pi e} B, \quad e \in E.$$

Such a change of splitting modifies the curvature $H$ by the exact form $dB$. Hence the cohomology class $[H] \in H^3(M, \mathbb{R})$, called the Severa class, is independent of the splitting and determines the exact Courant algebroid structure on $E$ completely.
2.2 Symmetries of the Courant bracket

The Lie bracket of smooth vector fields is invariant under diffeomorphisms; in fact, there are no other symmetries of the tangent bundle preserving the Lie bracket.

**Proposition 2.3.** Let $F$ be an automorphism of the tangent bundle covering the diffeomorphism $\varphi : M \to M$. If $F$ preserves the Lie bracket, then $F = \varphi_*$, the derivative of $\varphi$.

**Proof.** Let $G = \varphi_*^{-1} \circ F$, so that it is an automorphism of the Lie bracket covering the identity map. Then, for any vector fields $X, Y$ and $f \in C^\infty(M)$ we have $G([fX, Y]) = [G(fX), G(Y)]$. Expanding, we see that $Y(f)G(X) = G(Y)(f)G(X)$ for all $X, Y, f$. This can only hold when $G(Y) = Y$ for all vector fields $Y$, i.e. $G = Id$, yielding finally that $F = \varphi_*$. \qed

Since the Courant bracket on $T \oplus T^*$ depends on a 3-form $H$, it may appear at first glance to have a smaller symmetry group than the Lie bracket. However, as was observed in [35], the spinorial action of 2-forms [1.9] satisfies

$$e^{-B}dHe^B = d_{H+B},$$

and therefore we obtain the following action on derived brackets:

$$e^B[e^{-B} \cdot, e^{-B} \cdot]_H = [\cdot, \cdot]_{H+B}. \tag{2.6}$$

We see immediately from (2.6) that closed 2-forms act as symmetries of any exact Courant algebroid.

**Definition 2.4.** A B-field transformation is the automorphism of an exact Courant algebroid $E$ defined by a closed 2-form $B$ via

$$e \mapsto e + \pi^*\pi_e B.$$  

A diffeomorphism $\varphi : M \to M$ lifts to an orthogonal automorphism of $T \oplus T^*$ given by

$$\begin{pmatrix} \varphi_* & 0 \\ 0 & \varphi_*^{-1} \end{pmatrix},$$

which we will denote by $\varphi_*$. It acts on the Courant bracket via

$$\varphi_*[\varphi_*^{-1} \cdot, \varphi_*^{-1} \cdot]_H = [\cdot, \cdot]_{\varphi_*^{-1}H}. \tag{2.7}$$

Combining (2.7) with (2.6), we see that the composition $F = \varphi_* e^B$ is a symmetry of the $H$-twisted Courant bracket if and only if $\varphi^*H - H = dB$. We now show that such symmetries exhaust the automorphism group.

**Proposition 2.5.** Let $F$ be an orthogonal automorphism of $T \oplus T^*$, covering the diffeomorphism $\varphi : M \to M$, and preserving the $H$-twisted Courant bracket. Then $F = \varphi_* e^B$ for a unique 2-form $B \in \Omega^2(M)$ satisfying $\varphi^*H - H = dB$.

**Proof.** Let $G = \varphi_*^{-1} \circ F$, so that it is an automorphism of $T \oplus T^*$ covering the identity satisfying $G[G^{-1}, G^{-1}]_H = [\cdot, \cdot]_{\varphi^*H}$. In particular, for any sections $x, y \in C^\infty(T \oplus T^*)$ and $f \in C^\infty(M)$ we have $G[x, fy]_H = [Gx, Gfy]_{\varphi^*H}$, which, using axiom C3), implies

$$\pi(x)(f)Gy = \pi(Gx)(f)Gy.$$  

Therefore, $\pi G = \pi$, and so $G$ is an orthogonal map preserving projections to $T$. This forces it to be of the form $G = e^B$, for $B$ a uniquely determined 2-form. By (2.6), $B$ must satisfy $\varphi^*H - H = dB$. Hence we have $F = \varphi_* e^B$, as required. \qed
An immediate corollary of this result is that the automorphism group of an exact Courant algebroid $E$ is an extension of the diffeomorphisms preserving the cohomology class $[H]$ by the abelian group of closed 2-forms:

$$\begin{align*}
0 & \longrightarrow \Omega^2_{cl}(M) \longrightarrow \text{Aut}(E) \longrightarrow \text{Diff}_H(M) \longrightarrow 0.
\end{align*}$$

Derivations of a Courant algebroid $E$ are linear first order differential operators $D_X$ on $C^\infty(E)$, covering vector fields $X$ and satisfying

$$X\langle \cdot, \cdot \rangle = \langle D_X \cdot, \cdot \rangle + \langle \cdot, D_X \cdot \rangle,$$

$$D_X[\cdot, \cdot] = [D_X \cdot, \cdot] + [\cdot, D_X \cdot].$$

Differentiating a 1-parameter family of automorphisms $F_t = \varphi^t e^{B_t}$, $F_0 = \text{Id}$, and using the convention for Lie derivative

$$\mathcal{L}_X = -\frac{d}{dt}|_{t=0}\varphi^*_t,$$

we see that the Lie algebra of derivations of the $H$-twisted Courant bracket consists of pairs $(X, b) \in C^\infty(T) \oplus \Omega^2(M)$ such that $\mathcal{L}_X H = db$, which act via

$$(X, b) \cdot (Y + \eta) = \mathcal{L}_X (Y + \eta) - i_Y b.$$  \hfill (2.8)

Therefore the algebra of derivations of an exact Courant algebroid algebroid $E$ is an abelian extension of the smooth vector fields by the closed 2-forms:

$$\begin{align*}
0 & \longrightarrow \Omega^2_{cl}(M) \longrightarrow \text{Der}(E) \longrightarrow C^\infty(T) \longrightarrow 0.
\end{align*}$$

It is clear from axioms C1, C4) that the left adjoint action $\text{ad}_w : w \mapsto [v, w]$ defines a derivation of the Courant algebroid. However, $\text{ad}$ is neither surjective nor injective; rather, for $E$ exact, it induces the following exact sequence:

$$\begin{align*}
0 & \longrightarrow \Omega^1_{cl}(M) \overset{\pi^*}{\longrightarrow} C^\infty(E) \overset{\text{ad}}{\longrightarrow} \text{Der}(E) \overset{\chi}{\longrightarrow} H^2(M, \mathbb{R}) \longrightarrow 0,
\end{align*}$$

where $\Omega^1_{cl}(M)$ denotes the closed 1-forms and we define $\chi(D_X) = |i_X H - b| \in H^2(M, \mathbb{R})$ for $D_X = (X, b)$ as above.

The image of ad in sequence (2.9) defines a Lie subalgebra of $\text{Der}(E)$, and so suggests the definition of a subgroup of the automorphism group of $E$ analogous to the subgroup of Hamiltonian symplectomorphisms.

**Proposition 2.6.** Let $D_{X_t} = (X_t, b_t) \in C^\infty(T) \oplus \Omega^2(M)$ be a (possibly time-dependent) derivation of the $H$-twisted Courant bracket on a compact manifold, so that it satisfies $\mathcal{L}_{X_t} H = db_t$ and acts via (2.8). Then it generates a 1-parameter subgroup of Courant automorphisms

$$F^t_{D_X} = \varphi^t e^{B_t}, \quad t \in \mathbb{R},$$

where $\varphi^t$ denotes the flow of the vector field $X_t$ for a time $t$ and

$$B_t = \int_0^t \varphi_s^* b_t \, ds.$$ \hfill (2.10)

**Proof.** First we see that $F^t_{D_X}$ is indeed an automorphism, since

$$dB_t = \int_0^t \varphi_s^*(\mathcal{L}_{X_t} H) \, ds = \frac{d}{dt}|_{t=0} \int_0^t \varphi_s^* \varphi_u^* H \, ds$$

$$= \frac{d}{dt}|_{u=0} \int_0^{t+u} \varphi_s^* H \, ds'$$

$$= \varphi^*_t H - H,$$
which proves the result by Proposition 2.5. To see that it is a 1-parameter subgroup, observe that $e^B \varphi_s = \varphi_s e^{B_s}$ for any $\varphi \in \text{Diff}(M)$ and $B \in \Omega^2(M)$, so that

$$\varphi_s^t e^{B_1}\varphi_s^t e^{B_2} = \varphi^t_{s+t_2} e^{B_2 B_1} + \varphi_s^t e^{B_{s+t_2}} = \varphi_s^t e^{B_{s+t_2}},$$

where we use the expression (2.11) for the final equality.

Certain derivations $(X, b)$ are in the kernel of $\chi$ in (2.9), namely those for which $b = i_X H + d\xi$ for a 1-form $\xi$; we call these exact derivations. A smooth 1-parameter family of automorphisms $F_t = \varphi_t e^{B_t}$ from $F_0 = \text{id}$ to $F_1 = F$ is called an exact isotopy when it is generated by a smooth time-dependent family of exact derivations.

**Definition 2.7.** An automorphism $F \in \text{Aut}(E)$ is called exact if there is an exact isotopy $F_t$ from $F_0 = \text{id}$ to $F_1 = F$. This defines a subgroup of exact automorphisms of any Courant algebroid:

$$\text{Aut}_{ex}(E) \subset \text{Aut}(E).$$

If $\text{ad}(v_1)$ generates the exact isotopy $F_t$ and $F$ is any automorphism, then the conjugation $FF_t F^{-1}$ is also an exact isotopy, generated by the family of derivations

$$\text{ad}(F(v_1)).$$

Therefore we have the result that $\text{Aut}_{ex}(E)$ is a normal subgroup, in analogy with the group of Hamiltonian symplectomorphisms.

### 2.3 Relation to $S^1$-gerbes

The Courant bracket is part of a hierarchy of brackets on the bundles $T \oplus \wedge^p T^*$, $p = 0, 1, \ldots$, defined by the same formula

$$[X + \sigma, Y + \tau] = [X, Y] + \mathcal{L}_X \tau - i_Y d\sigma + i_X i_Y F,$$

where now $\sigma, \tau \in C^\infty(\wedge^p T^*)$ and $F$ is a closed form of degree $p + 2$.

For $p = 0$, the Courant bracket on $T \oplus 1$ is given by

$$[X + f, Y + g] = [X, Y] + Xg - Yf + i_X i_Y F. \quad (2.12)$$

When $F/2\pi$ is integral, we recognize this bracket as coming from the Atiyah Lie algebroid $\mathcal{A} = TP/S^1$ associated to a principal $S^1$ bundle $\pi : P \to M$, i.e.

$$
\begin{array}{c}
0 \longrightarrow 1 \longrightarrow \mathcal{A} \xrightarrow{\pi} TM \longrightarrow 0 ,
\end{array}
\quad (2.13)
$$

where $1 = \wedge^0 T^* M$ denotes the trivial line bundle over $M$. A splitting of this sequence provides a connection 1-form $\theta \in \Omega^1(P)$ with curvature $d\theta = \pi^* F$, and we see that the natural Lie bracket on $S^1$-invariant vector fields may be written, in horizontal and vertical components, as

$$[X_h + f \partial_t, Y_h + g \partial_t] = [X, Y] + (Xg - Yf + i_X i_Y F)\partial_t,$$

where $X \mapsto X_h$ denotes horizontal lift and $\partial_t$ is the vector field generating the principal $S^1$ action. In this way we recover the expression (2.12). The symmetries of $\mathcal{A}$ covering the identity consist of closed 1-forms $A$ acting via $X + f \mapsto X + f + i_X A$, which may be interpreted as the action of tensoring with a trivialization of a flat unitary line bundle. When $[A] \in H^1(M, \mathbb{Z})$, then it represents the action of a gauge transformation on $P$, modulo constant gauge transformations.

Just as a Lie algebroid of the form (2.13) may be associated with a $S^1$ bundle when $[F]/2\pi$ is integral, an exact Courant algebroid may be associated with a $S^1$ gerbe when $[H]/2\pi$ is...
integral. A $S^1$ gerbe may be specified, given an open cover \{U_i\}, by complex line bundles $L_{ij}$ on $U_i \cap U_j$ with isomorphisms $L_{ji} \cong L_{ij}^*$, and trivializations $\theta_{ijk}$ of $L_{ij} \otimes L_{jk} \otimes L_{ki}$ such that $\partial \theta = 1$ in the Cech complex. A 0-connection $\Phi$ on a gerbe is then specified by choosing connections $\nabla_{ij}$ on $L_{ij}$ such that the induced connection on threefold intersections obeys $\nabla \theta = 0$. Letting $F_{ij}$ be the curvature 2-forms of $\nabla_{ij}$, this implies that $\delta F = 0$, i.e.:

$$F_{ij} + F_{jk} + F_{ki} = 0.$$  \hfill (2.14)

As explained in [18], we may then construct an exact Courant algebroid $E$ as follows: glue $T \oplus T^*$ over $U_i$ with $T \oplus T^*$ over $U_j$ using the transition function $\Phi_{ij}$ given by the $B$-field transform

$$\Phi_{ij} = e^{F_{ij}}.$$  

By the cocycle condition $\Phi = 1$, we see that $\delta \Phi = 1$ and therefore it defines a bundle $E$. Since $\Phi_{ij}$ preserves projections to $T$, we see that $E$ is an extension of $T$ by $T^*$, as required. Finally, equipping $E|_{U_i}$ with the standard Courant bracket ($H = 0$) and inner product, we observe that since $\Phi_{ij}$ is orthogonal and preserves the Courant bracket, $E$ inherits the structure of an exact Courant algebroid. Choosing a splitting of the exact sequence then corresponds to the choice of 1-connection for the gerbe, i.e. the choice of local 2-forms $B_i$ such that $F = \delta B$. This then determines the global curvature 3-form of the gerbe $H = dB$, for which $H/2\pi$ is integral. In this sense, an exact Courant algebroid with integral curvature may be viewed as the generalized Atiyah sequence of a $S^1$ gerbe.

Similarly to the case of $p = 0$, the symmetries of $E$ covering the identity consist of closed 2-forms $B$ acting via $B$-field transforms, and these may be interpreted as trivializations of a flat gerbe. The difference of two such trivializations, a line bundle with connection, acts as a gauge transformation (integral $B$-field).

In the case that $F/2\pi$ is not integral, the Lie algebroid $\Phi$ may be interpreted as the Atiyah sequence of a trivialization of a $S^1$ gerbe with flat connection; similarly, a general exact Courant algebroid may be associated with a trivialization of a $S^1$ 2-gerbe with flat connection. The fact that such trivializations may be tensored together accounts for the Baer sum operation $[5]$ on exact Courant algebroids.

### 2.4 Dirac structures

The Courant bracket fails to be a Lie algebroid due to exact terms involving the inner product $\langle , \rangle$. Therefore, upon restriction to a subbundle $L \subset T \oplus T^*$ which is involutive (closed under the Courant bracket) as well as being isotropic, the anomalous terms vanish, and $(L, [\cdot , \cdot ], \pi)$ defines a Lie algebroid, with associated differential graded algebra $(\wedge^* L^*, d_L)$ just as the de Rham complex is associated to the canonical Lie algebroid structure on the tangent bundle.

In fact, the Courant bracket itself places a tight constraint on which proper subbundles may be involutive a priori:

**Proposition 2.8.** If $L \subset E$ is an involutive subbundle of an exact Courant algebroid, then $L$ must be isotropic, or of the form $\pi^{-1}(\Delta)$, for $\Delta$ an integrable distribution in $T$.

*Proof.* Suppose that $L \subset E$ is involutive, but not isotropic, i.e. there exists $v \in C^\infty(L)$ such that $\langle v, v \rangle \neq 0$ at some point $m \in M$. Then for any $f \in C^\infty(M)$,

$$[fv, v] = f[v, v] - (\pi(v)f)v + 2(v, v)df,$$

implying that $df|_m \in L|_m$ for all $f$, i.e. $T^*|_m \subset L|_m$. Since $T^*|_m$ is isotropic, this inclusion must be proper, i.e. $L|_m = \pi^{-1}(\Delta|_m)$, where $\Delta = \pi(L)$ is nontrivial at $m$. Hence the rank of $L$ must exceed the maximal dimension of an isotropic subbundle. This implies that $T^*|_m < L|_m$ at every point $m$, and hence that $\Delta$ is a smooth subbundle of $T$, which must itself be involutive. Hence $L = \pi^{-1}(\Delta)$, as required. \hfill $\square$
Definition 2.9 (Dirac structure). A maximal isotropic subbundle $L \subset E$ of an exact Courant algebroid is called an almost Dirac structure. If $L$ is involutive, then the almost Dirac structure is said to be integrable, or simply a Dirac structure.

The integrability of an almost Dirac structure $L$ may be expressed, following [11], as the vanishing of the operator $T_L(e_1,e_2,e_3) = ([e_1,e_2],e_3)$ on sections of $L$. Using the Clifford action we see that, for a local generator of the pure spinor line $K_L \subset \wedge^* T^*$ representing $L$, and sections $e_i \in C^\infty (L)$,

$$
\langle [e_1,e_2]_H,e_3 \rangle \varphi = [[d_H,e_1],e_2]_H \varphi = e_1 \cdot e_2 \cdot d_H \varphi.
$$

Therefore, as shown by Courant, integrability of a Dirac structure is determined by the vanishing of a tensor $T_L \in C^\infty (\wedge^3 L^*)$.

We see from Proposition 1.6 that at a point $p$, a Dirac structure $L \subset T \oplus T^*$ has a unique description as a generalized graph $\Gamma(L,\varepsilon)$, where $\Delta = \pi(L)$ is the projection to $T$ and $\varepsilon \in \wedge^2 \Delta^*$. Assuming that $L$ is regular near $p$ in the sense that $\Delta$ has constant rank near $p$, we have the following description of the integrability condition:

Proposition 2.10. Let $\Delta \subset T$ be a subbundle and $\varepsilon \in C^\infty (\wedge^2 \Delta^*)$. Then the almost Dirac structure $L(\Delta,\varepsilon)$ is integrable for the $H$-twisted Courant bracket if and only if $\Delta$ integrates to a foliation and $d_\Delta \varepsilon = i^* H$, where $d_\Delta$ is the leafwise exterior derivative.

Proof. Let $i : \Delta \hookrightarrow T$ be the inclusion. Then $d_\Delta : C^\infty (\wedge^k \Delta^*) \to C^\infty (\wedge^{k+1} \Delta^*)$ is defined by $i^* \circ d = d_\Delta \circ i^*$. Suppose that $X + \xi, Y + \eta \in C^\infty (L)$, i.e. $i^* \xi = i_X \varepsilon$ and $i^* \eta = i_Y \varepsilon$. Consider the bracket $Z + \zeta = [X + \xi, Y + \eta]$; if $L$ is Courant involutive, then $Z = [X,Y] \in C^\infty (\Delta)$, showing $\Delta$ is involutive, and the difference

$$
i^* \zeta - i_Z \varepsilon = i^* (\varepsilon \nabla_X \eta - \varepsilon \nabla_Y \xi + i_X i_Y H) - i [X,Y] \varepsilon
$$

$$
= d_\Delta i_X i_Y \varepsilon - i_X d_\Delta i_Y \varepsilon + i_Y d_\Delta i_X \varepsilon + i_X i_Y i^* H - [[d_\Delta, i_X], i_Y] \varepsilon
$$

$$
= i_Y i_X (d_\Delta \varepsilon - i^* H)
$$

must vanish for all $X + \xi, Y + \eta \in C^\infty (L)$, showing that $d_\Delta \varepsilon = i^* H$. Reversing the argument we see that the converse holds as well.

A consequence of this is that in a regular neighbourhood, a $d_H$-closed generator for the canonical line bundle may always be chosen:

Corollary 2.11. Let $(\Delta, \varepsilon)$ be as above and assume $L(\Delta,\varepsilon)$ is integrable; then for $B \in C^\infty (\wedge^2 T^*)$ such that $i^* B = -\varepsilon$, there exists a basis of sections $(\theta_1, \ldots, \theta_k)$ for $\text{Ann}(\Delta)$ such that

$$\varphi = e^B \theta_1 \wedge \cdots \wedge \theta_k$$

is a $d_H$-closed generator for the pure spinor line $K_L$.

Proof. Let $\Omega = \theta_1 \wedge \cdots \wedge \theta_k$. By Proposition 2.10 $\Delta$ is integrable, so $(\theta_1, \ldots, \theta_k)$ can be chosen such that $d\Omega = 0$. Then we have

$$d_H (e^B \Omega) = (dB + H) \wedge e^B \Omega = 0,$$

where the last equality holds since $i^* (dB + H) = -d_\Delta \varepsilon + i^* H = 0$.

In neighbourhoods where $\Delta$ is not regular, one may not find $d_H$-closed generators for $K_L$; nevertheless, one has the following useful description of the integrability condition. Recall that an almost Dirac structure $L \subset T \oplus T^*$ determines a filtration (1.11) of the forms $\wedge^* T^*$. By (2.15) we see that $d_H$ takes $C^\infty (F_0)$ into $C^\infty (F_3)$. The integrability of $L$, however, requires that $d_H$ take $C^\infty (F_0)$ into $C^\infty (F_1)$, as we now show.
**Theorem 2.12.** The almost Dirac structure \( L \subset T \oplus T^* \) is involutive for the \( H \)-twisted Courant bracket if and only if

\[
d_H(C^\infty(F_0)) \subset C^\infty(F_1),
\]

i.e. for any local trivialization \( \varphi \) of \( K_L \), there exists a section \( X + \xi \in C^\infty(T \oplus T^*) \) such that

\[
d_H\varphi = i_X \varphi + \xi \wedge \varphi.
\]

Furthermore, condition \((2.16)\) implies that

\[
d_H(C^\infty(F_k)) \subset C^\infty(F_{k+1})
\]

for all \( k \).

**Proof.** Let \( \varphi \) be a local generator for \( K_L = F_0 \). Then for \( e_1, e_2 \in C^\infty(L) \), we have

\[
[e_1, e_2]_H \cdot \varphi = [[d_H, e_1], e_2] \varphi = e_1 \cdot e_2 \cdot d_H \varphi,
\]

and therefore \( L \) is involutive if and only if \( d_H \varphi \) is annihilated by all products \( e_1 e_2, e_1 \in C^\infty(L) \).

Since \( F_1 \) is precisely the subbundle annihilated by products of \( k + 1 \) sections of \( L \), we obtain \( d_H \varphi \in F_1 \). The subbundle \( F_1 \) decomposes in even and odd degree parts as \( F_1 = F_0 \oplus (T \oplus T^*) \cdot F_0 \), and since \( d_H \) is of odd degree, we see that \( d_H \varphi \in (T \oplus T^*) \cdot K_L \), as required. To prove \((2.17)\), we proceed by induction on \( k \); let \( \psi \in F_k \), then since \( [e_1, e_2]_H \cdot \psi = [[d_H, e_1], e_2] \psi \), we have

\[
e_1 \cdot e_2 \cdot d_H \psi = d_H(e_1 \cdot e_2 \cdot \psi) + e_1 \cdot d_H(e_2 \cdot \psi) - e_2 \cdot d_H(e_1 \cdot \psi) - [e_1, e_2]_H \cdot \psi.
\]

All terms on the right hand side are in \( F_{k-1} \) by induction, implying that \( d_H \psi \in F_{k+1} \), as required. \( \square \)

Since the inner product provides a natural identification \( (T \oplus T^*) \cdot K_L = L^* \otimes K_L \), the previous result shows that the pure spinor line generating a Dirac structure is equipped with an operator

\[
d_H : C^\infty(K_L) \longrightarrow C^\infty(L^* \otimes K_L),
\]

which satisfies \( d^2_H = 0 \) upon extension to \( C^\infty(\wedge^k L^* \otimes K_L) \). This makes \( K_L \) a Lie algebroid module for \( L \), i.e. a module over the differential graded Lie algebra \( (\wedge^* L^*, d_L) \) associated to the Lie algebroid \( L \) (see \[15\] for discussion of Lie algebroid modules).

**Example 2.13.** The cotangent bundle \( T^* \subset T \oplus T^* \) is a Dirac structure for any twist \( H \in \Omega^2(M) \).

**Example 2.14.** The tangent bundle \( T \subset T \oplus T^* \) is itself maximal isotropic and involutive for the Courant bracket with \( H = 0 \), hence defines a Dirac structure. Applying any 2-form \( B \in \Omega^2(M) \), we obtain

\[
\Gamma_B = e^B(T) = \{X + i_X B : X \in T\},
\]

which is a Dirac structure for the \( dB \)-twisted Courant bracket. Indeed, \( T^* \) has no complementary Dirac structure unless \( |H| = 0 \).

**Example 2.15** (Twisted Poisson geometry). Applying a bivector field \( \beta \in C^\infty(\wedge^2 T) \) as in Example \[12\] to the Dirac structure \( T^* \), we obtain

\[
\Gamma_\beta = e^\beta(T^*) = \{i_\xi \beta + \xi : \xi \in T^*\}.
\]
As shown in [35], this almost Dirac structure is integrable with respect to the $H$-twisted Courant bracket if and only if
\[ [\beta, \beta] = \wedge^3 \beta^*(H), \]
where the bracket denotes the Schouten bracket of bivector fields. Such a structure is called a twisted Poisson structure, and becomes a usual Poisson structure when $\wedge^3 \beta^*(H) = 0$.

**Example 2.16** (Foliations). Let $\Delta \subset T$ be a smooth distribution of constant rank. Then the maximal isotropic subbundle
\[ \Delta \oplus \text{Ann}(\Delta) \subset T \oplus T^* \]
is Courant involutive if and only if $\Delta$ is integrable and $H|\Delta = 0$.

**Example 2.17** (Complex geometry). An almost complex structure $J \in \text{End}(T)$ determines a complex distribution, given by the $-i$-eigenbundle $T_{0,1} \subset T \otimes \mathbb{C}$ of $J$. Forming the maximal isotropic subbundle
\[ L_J = T_{0,1} \oplus \text{Ann}(T_{0,1}) = T_{0,1} \oplus T_{1,0}^*, \]
we see from Proposition 2.10 that $L_J$ is integrable if and only if $T_{0,1}$ is involutive and $i^*H = 0$ for the inclusion $i : T_{0,1} \hookrightarrow T \otimes \mathbb{C}$, i.e. $H$ is of type $(1,2) + (2,1)$. Viewing $H$ as the curvature of a gerbe, this means that the gerbe inherits a holomorphic structure compatible with the underlying complex manifold. In this way, integrable complex structures equipped with holomorphic gerbes can be described by (complex) Dirac structures.

We may apply Theorem 2.12 to give a simple description of the modular vector field of a Poisson structure (we follow [14]; for the case of twisted Poisson structures, see [25]). The Dirac structure (2.19) associated to a Poisson structure $\beta$ has corresponding pure spinor line generated by $\varphi = e^\beta \cdot v$, where $v \in C^\infty(\det T^*)$ is a volume form on the manifold, which we assume to be orientable. By Theorem 2.12, there exists $X + \xi \in C^\infty(T \oplus T^*)$ such that $d\varphi = (X + \xi) \cdot \varphi$. Since $L_\beta$ annihilates $\varphi$, there is a unique $X_v \in C^\infty(T)$, called the modular vector field associated to $(\beta, v)$, such that
\[ d\varphi = X_v \cdot \varphi. \quad (2.20) \]
We see from applying $d$ to (2.20) that
\[ \mathcal{L}_{X_v} \varphi = d(X_v \cdot \varphi) + X_v \cdot X_v \cdot \varphi = 0, \]
implying immediately that $X_v$ is a Poisson vector field (i.e. $[\beta, X_v] = 0$) preserving the volume form $v$. Of course the modular vector field is not an invariant of the Poisson structure alone; for $f \in C^\infty(M, \mathbb{R})$, one obtains
\[ X_{(e^f \cdot v)} = X_v + [\beta, f]. \]
As a result we see, following Weinstein [37], that $X_v$ defines a class $[X_v]$ in the first Lie algebroid cohomology of $\Gamma_\beta$, called the modular class of $\beta$:
\[ [X_v] \in H^1(M, \Gamma_\beta). \]

### 2.5 Tensor product of Dirac structures

We alluded in section 2.3 to a Baer sum operation on Courant algebroids; in this section we elaborate on the idea, and introduce an associated tensor product operation on Dirac structures, which will be used in Section 3.4. This operation was noticed independently by the authors of [3], who use it to describe some remarkable properties of Dirac structures on Lie groups.
Like gerbes, exact Courant algebroids may be pulled back to submanifolds \( \iota : S \hookrightarrow M \). Following \cite{[7]}, we provide a proof in the Appendix. It is shown there that if \( E \) is an exact Courant algebroid on \( M \), then

\[
\iota^* E := K^\perp / K,
\]

where \( K = \text{Ann}(TS) \) and \( K^\perp \) is the orthogonal complement in \( E \), inherits an exact Courant algebroid structure over \( S \), with Ševera class given simply by the pullback along the inclusion. Furthermore, any Dirac structure \( L \subset E \) may be pulled back to \( S \) via

\[
\iota^* L_S := \frac{L \cap K^\perp + K}{K} \subset \iota^* E, \tag{2.21}
\]

which is an integrable Dirac structure whenever it is smooth as a subbundle of \( \iota^* E \), e.g. if \( L \cap K^\perp \) has constant rank on \( S \) (see the Appendix, Proposition \cite{[7.2]}, for a proof).

Let \( E, F \) be exact Courant algebroids over the same manifold \( M \). Then \( E \times F \) is naturally an exact Courant algebroid over \( M \times M \), and may be pulled back by the diagonal embedding \( d : M \hookrightarrow M \times M \). The result coincides with the Baer sum of \( E \) and \( F \) as defined in \cite{[5]}, and we denote it as follows.

**Definition 2.18.** Let \( E_1, E_2 \) be exact Courant algebroids over the same manifold \( M \), and let \( d : M \hookrightarrow M \times M \) be the diagonal embedding. Then we define the *Baer sum* or *tensor product* of \( E_1 \) with \( E_2 \) to be the exact Courant algebroid (over \( M \))

\[
E_1 \boxtimes E_2 = d^*(E_1 \times E_2),
\]

which can be written simply as

\[
E_1 \boxtimes E_2 = \{(e_1, e_2) \in E_1 \times E_2 : \pi_1(e_1) = \pi_2(e_2)\} / \{(-\pi_1^* \xi, \pi_2^* \xi) : \xi \in T^*\},
\]

and has Ševera class equal to the sum \([H_1] + [H_2]\).

The standard Courant algebroid \((T \oplus T^*, [\cdot, \cdot])_0\) acts as an identity element for this operation, and every exact Courant algebroid \( E \) has a natural inverse, denoted by \( E^\top \), defined as the same Courant algebroid with \( \langle \cdot, \cdot \rangle \) replaced with its negative \(-\langle \cdot, \cdot \rangle\):

\[
E^\top = (E, [\cdot, \cdot], -\langle \cdot, \cdot \rangle, \pi). \tag{2.22}
\]

Note that this sign reversal changes the sign of \( \pi^* : T^* \longrightarrow E \) and hence of the curvature \( H \) of any splitting \((2.5)\), and finally therefore of the Ševera class.

**Proposition 2.19.** Let \( E^\top \) be as above. Then we have a canonical isomorphism

\[
E^\top \boxtimes E = (T \oplus T^*, [\cdot, \cdot])_0.
\]

*Proof.* \( E^\top \boxtimes E \) has a well-defined, bracket-preserving splitting \( s : T \longrightarrow E^\top \boxtimes E \) given by \( X \mapsto [(e_X, e_X)] \) for any \( e_X \in E \) such that \( \pi(e_X) = X \). \( \square \)

We may now use the Dirac pullback \((2.21)\) to define the tensor product of Dirac structures; an equivalent definition appears in \cite{[3]}.

**Definition 2.20.** Let \( L_1 \subset E_1, L_2 \subset E_2 \) be Dirac structures and \( E_1, E_2 \) as above. We define the *tensor product*

\[
L_1 \boxtimes L_2 = d^*(L_1 \times L_2) \subset E_1 \boxtimes E_2,
\]

where \( d^* \) denotes the Dirac pullback \((2.21)\) by the diagonal embedding. Explicitly, we have

\[
L_1 \boxtimes L_2 = \{(x_1, x_2) \in L_1 \times L_2 : \pi_1(x_1) = \pi_2(x_2)\} + K / K, \tag{2.23}
\]

where \( K = \{(-\pi_1^* \xi, \pi_2^* \xi) : \xi \in T^*\} \). This forms a Dirac structure whenever it is smooth as a bundle.
Example 2.21. The canonical Dirac structure $T^* \subset E$ acts as a zero element: for any other Dirac structure $L \subset F$,

$$T^* \boxtimes L = T^* \subset E \boxtimes F.$$ 

Example 2.22. The Dirac structure $\Delta + \text{Ann}(\Delta) \subset T \oplus T^*$ associated to an integrable distribution $\Delta \subset T$ is idempotent:

$$(\Delta + \text{Ann}(\Delta)) \boxtimes (\Delta + \text{Ann}(\Delta)) = \Delta + \text{Ann}(\Delta).$$

Example 2.23. The tensor product of Dirac structures is compatible with B-field transformations:

$$e^{B_1} L_1 \boxtimes e^{B_2} L_2 = e^{B_1 + B_2} (L_1 \boxtimes L_2).$$

Combining this with the previous example, taking $\Delta = T$, we see that Dirac structures transverse to $T^*$ remain so after tensor product. Finally we provide an example where smoothness is not guaranteed.

Example 2.24. Let $L \subset E$ be any Dirac structure, with $L^\top \subset E^\top$ defined by the inclusion $L \subset E$. Then

$$L^\top \boxtimes L = \Delta + \text{Ann}(\Delta) \subset T \oplus T^*,$$

where $\Delta = \pi(L)$. Hence $L^\top \boxtimes L$ is a Dirac structure when $\Delta + \text{Ann}(\Delta)$ is a smooth subbundle, i.e. when $\Delta$ has constant rank.

Assuming we choose splittings for $E_1, E_2$, the tensor product of Dirac structures $L_1 \subset E_1, L_2 \subset E_2$ annihilates the wedge product $K_1 \wedge K_2$ of the pure spinor lines representing $L_1$ and $L_2$. For reasons of skew-symmetry, $K_1 \wedge K_2$ is nonzero only when $L_1 \cap L_2 \cap T^* = \{0\}$. This result also appears in [3]:

Proposition 2.25. Let $L_1, L_2$ be Dirac structures in $T \oplus T^*$, and let $\varphi_1 \in K_1, \varphi_2 \in K_2$ be (local) generators for their corresponding pure spinor lines in $\wedge^* T^*$. Then

$$L_1 \boxtimes L_2 \cdot (\varphi_1 \wedge \varphi_2) = 0,$$

and therefore $\varphi_1 \wedge \varphi_2$ is a pure spinor for $L_1 \boxtimes L_2$ as long as $L_1 \cap L_2 \cap T^* = \{0\}$.

Proof. From expression (2.23), we obtain the following simple expression:

$$L_1 \boxtimes L_2 = \{X + \xi + \eta : X + \xi \in L_1 \text{ and } X + \eta \in L_2\}. \quad (2.24)$$

Then for $X + \xi + \eta \in L_1 \boxtimes L_2$, we have

$$(X + \xi + \eta) \cdot (\varphi_1 \wedge \varphi_2) = (i_X \varphi_1 + \xi \wedge \varphi_1) \wedge \varphi_2 + (-1)^{|\varphi_1|} \varphi_1 \wedge (i_X \varphi_2 + \eta \wedge \varphi_2) = 0.$$ 

\[\square\]

There is an anti-orthogonal map $T \oplus T^* \to T \oplus T^*$ given by

$$X + \xi \mapsto (X + \xi)^\top = X - \xi$$

which satisfies

$$[(X + \xi)^\top, (Y + \eta)^\top]^\top_H = [X + \xi, Y + \eta]_{-H},$$

so that it takes the Courant algebroid to its inverse \(2.22\). This operation intertwines with the Clifford reversal, in the sense that

$$((X + \xi) \cdot \varphi)^\top = (-1)^{|\varphi|+1}(X + \xi)^\top \cdot \varphi^\top,$$

20
for any \( \varphi \in \wedge^T \), where \( |\varphi| \) denotes the degree. As a result, we see that reversal operation on forms corresponds to the reversal \( L \mapsto L^\top \) of Dirac structures in \( T \oplus T^* \). Since the Mukai pairing of pure spinors \( \varphi, \psi \), is given by the top degree component of \( \varphi^\top \wedge \psi \), we conclude from Propositions 1.17 and 1.18 that for transverse Dirac structures \( L_1, L_2 \subset E \) the tensor product \( L_1^\top \otimes L_2 \subset T \oplus T^* \) has zero intersection with \( T \) and hence is the graph of a Poisson bivector \( \beta \). This result was first observed in its general form in \([3]\), and is consistent with the appearance of a Poisson structure associated to any Lie bialgebroid in \([29]\).

**Proposition 2.26** (Alekseev-Bursztyn-Meinrenken \([3]\)). Let \( E \) be any exact Courant algebroid and \( L_1, L_2 \subset E \) be transverse Dirac structures. Then
\[
L_1^\top \otimes L_2 = \Gamma_\beta \subset T \oplus T^*,
\]
where \( \beta \in C^\infty(\wedge^2 T) \) is a Poisson structure.

### 3 Generalized complex structures

Just as a complex structure may be defined as an endomorphism \( J : T \rightarrow T \) satisfying \( J^2 = -1 \) and which is integrable with respect to the Lie bracket, we have the following definition, due to Hitchin \([18]\):

**Definition 3.1.** A generalized complex structure on an exact Courant algebroid \( E \cong T \oplus T^* \) is an endomorphism \( J : E \rightarrow E \) satisfying \( J^2 = -1 \) and which is integrable with respect to the Courant bracket, i.e. its \(+i\) eigenbundle \( L \subset E \otimes \mathbb{C} \) is involutive.

An immediate consequence of Proposition 2.8 is that the \(+i\) eigenbundle of a generalized complex structure must be isotropic, implying that \( J \) must be orthogonal with respect to the natural pairing on \( E \):

**Proposition 3.2.** A generalized complex structure \( J \) must be orthogonal, and hence defines a symplectic form \( \langle J \cdot, \cdot \rangle \) on \( E \).

**Proof.** Let \( x, y \in C^\infty(E) \) and decompose \( x = a + \bar{a}, y = b + \bar{b} \) according to the polarization \( E \otimes \mathbb{C} = L \oplus \bar{L} \). Since \( L \) must be isotropic by Proposition 2.8
\[
\langle Jx, y \rangle = \langle a, \bar{b} \rangle + \langle \bar{a}, b \rangle = \langle x, y \rangle.
\]
Hence \( J \) is orthogonal and \( \langle J \cdot, \cdot \rangle \) is symplectic, as required. \( \square \)

This equivalence between complex and symplectic structures on \( E \) compatible with the inner product is illustrated most clearly by examining two extremal cases of generalized complex structures on \( T \oplus T^* \). First, consider the endomorphism of \( T \oplus T^* \):

\[
J_J = \begin{pmatrix}
-J & 0 \\
0 & J^*
\end{pmatrix},
\]
where \( J \) is a usual complex structure on \( V \). Then we see that \( J_J^2 = -1 \) and \( J_J^* = -J_J \). Its \(+i\) eigenbundle \( L_J = T_{0,1} \oplus T_{1,0}^* \) is, by Example 2.17 integrable if and only if \( J \) is integrable and \( H^{(3,0)} = 0 \).

At the other extreme, consider the endomorphism
\[
J_\omega = \begin{pmatrix}
0 & -\omega^{-1} \\
\omega & 0
\end{pmatrix},
\]
where \( \omega \) is a usual symplectic structure. Again, we observe that \( J_\omega^2 = -1 \) and the \(+i\) eigenbundle
\[
L_\omega = \{ X - i\omega(X) : X \in T \otimes \mathbb{C} \}.
\]

21
is integrable, by Example 2.14 if and only if $H = 0$ and $d\omega = 0$.

Therefore we see that diagonal and anti-diagonal generalized complex structures correspond to complex and symplectic structures, respectively. We now make some elementary observations concerning the general case.

**Proposition 3.3.** Generalized complex manifolds must be even-dimensional.

**Proof.** Let $p \in M$ be any point and $E_p$ the fibre of the exact Courant algebroid at $p$. Let $x \in E_p$ be null, i.e. $(x, x) = 0$. Then $Jx$ is also null and is orthogonal to $x$. Therefore $\{x, Jx\}$ span an isotropic subspace $N \subset E_p$. We may iteratively enlarge the spanning set by adding a pair $\{x', Jx'\}$ for $x' \in N^\perp$, until $N^+ = N$ and $\dim M = \dim N$ is even. \hfill $\square$

At any point $p \in M$, the orthogonal group $O(E_p) \cong O(2n, 2n)$ acts transitively on the space of generalized complex structures at $p$ by conjugation, with stabilizer $U(n, n) = O(2n, 2n) \cap GL(2n, \mathbb{C})$. Therefore the space of generalized complex structures at $p$ is given by the coset space

$$O(2n, 2n) \bigg/ U(n, n).$$

In this sense, a generalized complex structure on an even-dimensional manifold is an integrable reduction of the structure group of $E$ from $O(2n, 2n)$ to $U(n, n)$. Since $U(n, n)$ is homotopic to $U(n) \times U(n)$, the $U(n, n)$ structure may be further reduced to $U(n) \times U(n)$, which corresponds geometrically to the choice of a positive definite subbundle $C_+ \subset E$ which is complex with respect to $J$. The orthogonal complement $C_- = C_\perp$ is negative-definite and also complex, and so we obtain the orthogonal decomposition

$$E = C_+ \oplus C_-.$$  

Note that since $C_\pm$ are definite and $T^* \subset E$ is isotropic, the projection $\pi : C_\pm \to T$ is an isomorphism. Hence we can transport the complex structures on $C_\pm$ to $T$, obtaining two almost complex structures $J_+, J_-$ on $T$. Thus we see that a generalized complex manifold must admit an almost complex structure. Furthermore it has two canonically associated sets of Chern classes $c^\pm_i = c_i(T, J_\pm) \in H^{2i}(M, \mathbb{Z})$. Summarizing, and using (3.4), we obtain the following.

**Proposition 3.4.** A generalized complex manifold must admit almost complex structures, and has two sets of canonical classes $c^\pm_i \in H^{2i}(M, \mathbb{Z})$ such that the total Chern class

$$c(E, J) = c^+ \cup c^-,$$

where $c^\pm = \sum_i c^\pm_i$.

### 3.1 Type and the canonical line bundle

Any exact Courant algebroid has a canonical Dirac structure $T^* \subset E$, and a generalized complex structure $J$ may be characterized by its action on this Dirac structure, as we now describe.

If $JT^* = T^*$, then $J$ determines a usual complex structure on the manifold, and a splitting may be chosen for $E$ so that $J$ is of the form (3.1). On the other hand, if $JT^* \cap T^* = \{0\}$, then we have the canonical splitting $E = JT^* \oplus T^*$, and $J$ takes the form (3.2), i.e. a symplectic structure.

In general, the subbundle $JT^* \subset E$ projects to a distribution

$$\Delta = \pi(JT^*) \subset T$$

(3.5)
which may vary in dimension along the manifold. Defining

\[ E_\Delta = \frac{T^* + J T^*}{\text{Ann}(\Delta)}, \]

we see that \( E_\Delta \) is an extension of the form

\[ \begin{array}{cccccc}
0 & \longrightarrow & \Delta^* & \longrightarrow & E_\Delta & \longrightarrow & \Delta & \longrightarrow & 0, \\
& & & & \pi & & \\
& & & & \Delta & & \\
\end{array} \]

and since \( \text{Ann}(\Delta) = T^* \cap J T^* \) is complex, we see that \( J \) induces a complex structure on \( E_\Delta \) such that \( J \Delta^* \cap \Delta^* = \{0\} \). Therefore, at each point, \( \Delta \) inherits a generalized complex structure of symplectic type. Furthermore,

\[ \frac{E}{T^* + J T^*} = T/\Delta, \]

showing that, at each point, \( T/\Delta \) inherits a complex structure. Ignoring integrability, which we address in the next section, we may therefore conclude that a generalized complex manifold carries a canonical symplectic distribution (of variable dimension) with transverse complex structure.

The invariant of \( J \) measuring the number of transverse complex directions at each point is called the type of the generalized complex structure \( J \) is the upper semi-continuous function

\[ \text{type}(J) = \frac{1}{2} \dim_{\mathbb{R}} T^* \cap J T^*, \]

with possible values \( \{0, 1, \ldots, n\} \), where \( n = \frac{1}{2} \dim_{\mathbb{R}} M \).

**Definition 3.5.** The type of the generalized complex structure \( J \) is the upper semi-continuous function

\[ \text{type}(J) = \frac{1}{2} \dim_{\mathbb{R}} T^* \cap J T^*, \]

with possible values \( \{0, 1, \ldots, n\} \), where \( n = \frac{1}{2} \dim_{\mathbb{R}} M \).

The terminology is chosen to coincide with the notion of type for Dirac structures (see Definition 1.17), since it is indeed the type of the Dirac structure \( L \subset E \otimes \mathbb{C} \) defining \( J \):

**Proposition 3.6.** The type of \( J \) coincides with the type of its \(+i\) eigenbundle \( L \subset E \otimes \mathbb{C} \), and hence is of fixed parity throughout the manifold.

**Proof.** At any point, the subspace \( T^* \cap J T^* \) is complex, and hence

\[ (T^* \cap J T^*) \otimes \mathbb{C} = A \otimes \bar{A}, \]

where \( A = L \cap (T^* \otimes \mathbb{C}) \). Since \( \text{type}(L) = \dim_{\mathbb{C}} L \cap (T^* \otimes \mathbb{C}) \), we see that \( \text{type}(J) = \text{type}(L) \), as required. By Proposition 1.18 the parity of \( \text{type}(J) \) must be fixed throughout the manifold. \( \Box \)

As a result, we see that in real dimension 2, connected generalized complex manifolds must be of constant type 0 or 1, i.e. of symplectic or complex type, whereas in dimension 4, they may be of types 0, 1, or 2, with possible jumping from 0 (symplectic) to 2 (complex) along closed subsets of the manifold; we shall encounter such examples in sections 4.1 and 5.3.

It also follows from our work on Dirac structures that a generalized complex structure is completely characterized by the pure spinor line \( K \subset S \otimes \mathbb{C} \) corresponding to the maximal isotropic subbundle \( L \). When a splitting for \( E \) is chosen, we obtain an identification \( S = \wedge^* T^* \otimes (\det T)^{1/2} \), and hence \( K \) may be viewed as a line subbundle of the complex differential forms. For a symplectic structure, \( L_\omega = e^{-i\omega}(T) \), and so

\[ K_\omega = e^{-i\omega} \cdot \wedge^0 T^* = \mathbb{C} \cdot e^{i\omega}, \]

whereas for a complex structure \( L_J = T_{0,1} + T_{1,0}^* \), so that

\[ K_J = \wedge^n T_{1,0}^*, \]

leading to the following definition.
Definition 3.7. The canonical line bundle of a generalized complex structure on $T \oplus T^*$ is the complex pure spinor line subbundle $K \subset \wedge^* T^* \otimes \mathbb{C}$ annihilated by the $+i$ eigenbundle $L$ of $\mathcal{J}$.

Proposition 3.15 states that a generator $\varphi \in K_x$ for the canonical line bundle at the point $x \in M$ must have the form

$$\varphi = e^{B+i\omega}\Omega, \quad (3.6)$$

where $\varphi = \theta_1 \wedge \cdots \wedge \theta_k$ for $(\theta_1, \ldots, \theta_k)$ a basis for $L \cap (T^* \otimes \mathbb{C})$, and $B, \omega$ are the real and imaginary components of a complex 2-form. As a result we can read off the type of $\mathcal{J}$ at $p$ directly as the least nonzero degree ($k$) of the differential form $\varphi$. The generalized complex structure defines a polarization $E \otimes \mathbb{C} = L \oplus \overline{L}$.,

and therefore by Proposition 1.17,

$$\langle \varphi, \overline{\varphi} \rangle \neq 0, \quad (3.8)$$

Using (3.6), we obtain

$$0 \neq (e^{B+i\omega}\Omega, e^{B-i\omega}\overline{\Omega}) = (e^{2i\omega}\Omega, \overline{\Omega})$$

$$= (-1)^{2(k-2)(n-k)}(n-k)!\omega^{n-k} \wedge \Omega \wedge \overline{\Omega},$$

which expresses the fact that $\omega$ pulls back to the symplectic form on $\Delta = \ker \Omega \wedge \overline{\Omega}$ described earlier, and $\Omega$ defines the complex structure transverse to $\Delta$. We also see that $\langle \varphi, \overline{\varphi} \rangle \in \det T^*$ defines an orientation independent of the choice of $\varphi$, giving a global orientation on the manifold. This orientation, together with the parity of the type, defines a pair of invariants which distinguish the four connected components of the coset space $\mathcal{J}/\mathcal{J}$.

In the following result, we show that at any point, a splitting for $E$ may be chosen so that the generalized complex structure is a product of a complex and a symplectic structure of lesser dimension.

Theorem 3.8. At any point, a generalized complex structure of type $k$ is equivalent, by a choice of splitting for $E$, to the direct sum of a complex structure of complex dimension $k$ and a symplectic structure of real dimension $2n - 2k$.

Proof. Fixing a splitting for $E$ at $x \in M$, the generalized complex structure is defined, as in (3.6), by the pure spinor

$$\varphi = e^{B+i\omega}\Omega,$$

where $\omega^{n-k} \wedge \Omega \wedge \overline{\Omega} \neq 0$. Choose a subspace $N \subset T_x$ transverse to $\Delta = \ker \Omega \wedge \overline{\Omega}$. Then $\Delta$ carries a symplectic structure $\omega_0 = \omega|\Delta$ and $N$ inherits a complex structure determined by $\Omega|N$. The 2-forms then decompose as

$$\wedge^2 T^*_x = \bigoplus_{p+q+r=2} \wedge^p \Delta^* \otimes \wedge^q N^*_{1,0} \otimes \wedge^r N^*_{0,1},$$

so that forms have tri-degree $(p, q, r)$. While $\Omega$ is purely of type $(0, k, 0)$, the complex 2-form $A = B + i\omega$ decomposes into six components:

$$A^{200}, A^{110}, A^{101}, A^{020}, A^{011}, A^{002}$$

Only the components $A^{200}, A^{101}, A^{002}$ act nontrivially on $\Omega$ in the expression $e^A\Omega$. Hence we are free to modify the other three components at will. Note that $\omega_0 = -\frac{i}{2}(A^{200} - \overline{A^{200}})$. Now define the real 2-form

$$\tilde{B} = \frac{1}{2}(A^{200} + \overline{A^{200}}) + A^{101} + \overline{A^{101}} + A^{002} + \overline{A^{002}},$$
and observe that $e^{B+i\omega_0}\Omega = e^{\tilde{B}+i\omega_0}\Omega$, demonstrating that $\varphi = e^{\tilde{B}+i\omega_0}\Omega$, i.e. $\varphi$ is a B-field transform of $e^{i\omega_0}\Omega$, which is a direct sum of a symplectic structure on $\Delta$ and complex structure on $N$, as required.

The canonical line bundle $K$ introduced in this section, along with its complex conjugate $\overline{K}$, are the extremal line bundles of a $\mathbb{Z}$-grading on spinors induced by the generalized complex structure. As described in (1.16), a polarization induces a $\mathbb{Z}$-grading on spinors; therefore a generalized complex structure on $T \oplus T^*$, since it determines a polarization $(T \oplus T^*) \otimes \mathbb{C} = L \oplus \overline{L}$, induces an alternative $\mathbb{Z}$-grading on differential forms

$$\wedge^* T^* \otimes \mathbb{C} = U^{-n} \oplus \cdots \oplus U^n,$$

where $U^n = K$ is the canonical line bundle and $U^{n-k} = \wedge^k \overline{L} \cdot U^n$. Since $\overline{L}$ annihilates $U^{-n}$, we see that $U^{-n} = U^n$ is the canonical line of $-J$. We therefore have the following convenient description of this $\mathbb{Z}$-grading.

**Proposition 3.9.** A generalized complex structure $J$ on $E = T \oplus T^*$ gives rise to a $\mathbb{Z}$-grading

$$\wedge^* T^* \otimes \mathbb{C} = U^{-n} \oplus \cdots \oplus U^n,$$

where $U^k$ is the $ik$-eigenbundle of $J$ acting in the spin representation, and $U^n = K$, the canonical line bundle.

In the case of a usual complex structure $J_J$, then the graded components correspond to the well-known $(p,q)$-decomposition of forms as follows:

$$U^k_J = \bigoplus_{p-q=k} \Omega^{p,q}(M, \mathbb{C}), \quad (3.9)$$

since $J_J$ acts via the spin representation as $J^*$, which has eigenvalue $i(p - q)$ on $\Omega^{p,q}$.

The fact that $U^{-n} = \det \overline{L} \cdot U^n$, combined with our previous remark (3.8), implies that

$$U^n \otimes \det L^* \otimes U^n \cong \det T^* \otimes \mathbb{C}.$$

Since the complex bundle $L$ is isomorphic to $(E, J)$, we obtain the following.

**Corollary 3.10.** The canonical line bundle of a generalized complex manifold has first Chern class satisfying

$$2c_1(K) = c_1^+ + c_1^-.$$

### 3.2 Courant Integrability

The notion of type and the $\mathbb{Z}$-grading on spinors introduced in the last section do not depend on the Courant integrability of the generalized complex structure; they may be associated to any generalized almost complex structure:

**Definition 3.11.** A generalized almost complex structure is a complex structure $J$ on an exact Courant algebroid which is orthogonal with respect to the natural inner product.

Naturally, a generalized almost complex structure $J$ is said to be integrable when its $+i$ eigenbundle $L \subset E \otimes \mathbb{C}$ is involutive for the Courant bracket, i.e. $L$ is a Dirac structure.

**Proposition 3.12.** A generalized complex structure is equivalent to a complex Dirac structure $L \subset E \otimes \mathbb{C}$ such that $L \cap \overline{L} = \{0\}.$
As a result, \((L, [\cdot, \cdot], \pi)\), where \(\pi : L \rightarrow T \otimes \mathbb{C}\) is the projection, defines the structure of a Lie algebroid, and therefore we obtain a differential complex
\[
C^\infty(\wedge^k L^*) \xrightarrow{d_L} C^\infty(\wedge^{k+1} L^*),
\]
where \(d_L\) is the Lie algebroid de Rham differential, which satisfies \(d_L^2 = 0\) due to the Jacobi identity for the Courant bracket restricted to \(L\). The operator \(d_L\) has principal symbol \(s(d_L) : T^* \otimes \wedge^k L^* \rightarrow \wedge^{k+1} L^*\) given by \(\pi^*(\xi) \wedge \cdot\), where \(\xi \in T^*\). We now observe that the complex (3.10) is elliptic for a generalized complex structure.

**Proposition 3.13.** The Lie algebroid complex of a generalized complex structure is elliptic.

**Proof.** Given a real, nonzero covector \(\xi \in T^*\), write \(\xi = \alpha + \beta\) for \(\alpha \in L^*\). For \(v \in L\), we have \(\pi^*(\xi(v)) = (\xi, v) = (\alpha, v)\). Using the inner product to identify \(L^* = \mathbb{L}\), we therefore have \(\pi^*(\xi) = \alpha\), which is clearly nonzero if and only if \(\xi\) is. As a result, the symbol sequence is exact for any nonzero real covector, as required.

This provides us with our first invariants associated to a generalized complex structure:

**Corollary 3.14.** The cohomology of the complex (3.10), called the Lie algebroid cohomology \(H^\bullet(M, L)\), is a finite dimensional graded ring associated to any compact generalized complex manifold.

In the case of a complex structure, \(L = T_{0,1} \oplus T^*_{1,0}\), while \(d_L = \overline{\partial}\), and so the Lie algebroid complex is a sum of usual Dolbeault complexes, yielding
\[
H^k(M, L_J) = \bigoplus_{p+q=k} H^p(M, \wedge^q T_{1,0}).
\]

In the case of a symplectic structure, the Lie algebroid \(L\) is the graph of \(i\omega\), and hence is isomorphic to \(T \otimes \mathbb{C}\) as a Lie algebroid. Hence its Lie algebroid cohomology is simply the complex de Rham cohomology.
\[
H^k(M, L_\omega) = H^k(M, \mathbb{C}).
\]

We now describe a second invariant, obtained from the \(\mathbb{Z}\)-grading on differential forms induced by \(J\). As we saw in the previous section, a generalized complex structure on \(T \oplus T^*\) determines an alternative grading for the differential forms
\[
\wedge^* T^* \otimes \mathbb{C} = U^{-n} \oplus \cdots \oplus U^n.
\]

This \(\mathbb{Z}\)-grading may be viewed as the intersection of two complex conjugate filtrations
\[
F_i = \oplus_{k=0}^i U^{n-k}, \quad \overline{F}_i = \oplus_{k=0}^i U^{-n+k}.
\]

More precisely, we have
\[
U^k = F_{-k} \cap \overline{F}_{-k}.
\]

By Theorem 2.16, the integrability of \(J\) with respect to \([\cdot, \cdot]_H\) is equivalent to the fact that \(d_H\) takes \(C^\infty(F_i)\) into \(C^\infty(F_{i+1})\). Using (3.11), this happens if and only if \(d_H\) takes \(C^\infty(U^k)\) into \(C^\infty(U^{k-1} \oplus U^k \oplus U^{k+1})\), but since \(d_H\) is odd, we see that \(J\) is integrable if and only
if $d_H(C^\infty(U^k)) \subset C^\infty(U^{k-1} \oplus U^{k+1})$. Projecting to these two components, we obtain $d_H = \partial + \overline{\partial}$, where

$$C^\infty(U^k) \xrightarrow{\partial} C^\infty(U^{k+1}).$$

(3.12)

In greater generality, we may use our calculation in (2.15) to obtain the following.

**Theorem 3.15.** Let $\mathcal{J}$ be a generalized almost complex structure on $T \oplus T^*$, and define

$$\partial = \pi_{k+1} \circ d_H : C^\infty(U^k) \rightarrow C^\infty(U^{k+1})$$

$$\overline{\partial} = \pi_{k-1} \circ d_H : C^\infty(U^k) \rightarrow C^\infty(U^{k-1}),$$

where $\pi_k$ is the projection onto $U^k$. Then

$$d_H = \partial + \overline{\partial} = T_L + \overline{T_L},$$

(3.13)

where $T_L \in \wedge^3 L^* = \wedge^3 T$ is defined by

$$T_L(e_1, e_2, e_3) = ([e_1, e_2], e_3),$$

and acts via the Clifford action in (3.13). $\mathcal{J}$ is integrable, therefore, if and only if $d_H = \partial + \overline{\partial}$, or equivalently, if and only if

$$d_H(C^\infty(U^n)) \subset C^\infty(U^{n-1}).$$

(3.14)

In the integrable case, since $d_H = \partial + \overline{\partial}$ and $d_H^2 = 0$, we conclude that $\partial^2 = \overline{\partial}^2 = 0$ and $\partial \overline{\partial} = -\overline{\partial} \partial$; hence in each direction, (3.12) defines a differential complex.

**Remark.** Given the above, a generalized complex structure gives rise to a real differential operator $d^{\mathcal{J}} = i(\overline{\partial} - \partial)$, which can also be written $d^{\mathcal{J}} = [d, \mathcal{J}]$, and which satisfies $(d^{\mathcal{J}})^2 = 0$. It is interesting to note that while in the complex case $d^{\mathcal{J}}$ is just the usual $d$-operator $d = i(\overline{\partial} - \partial)$, in the symplectic case $d^{\mathcal{J}}$ is equal to the symplectic adjoint of $d$ defined by Koszul [26] and studied by Brylinski [9] in the context of symplectic harmonic forms.

Using the identification $U^{n-k} = \wedge^k L^* \otimes K$ as in (1.16), the operator $\overline{\partial}$ can be viewed as a Lie algebroid connection

$$\overline{\partial} : C^\infty(\wedge^k L^* \otimes K) \rightarrow C^\infty(\wedge^{k+1} L^* \otimes K),$$

extended from $d_H : C^\infty(K) \rightarrow C^\infty(L^* \otimes K)$ via the rule

$$\overline{\partial}(\mu \otimes s) = d_L (\mu \otimes s) + (-1)^{|\mu|} \mu \wedge ds,$$

(3.15)

for $\mu \in C^\infty(\wedge^k L^*)$ and $s \in C^\infty(K)$, and satisfying $\overline{\partial}^2 = 0$. Therefore $K$ is a module for the Lie algebroid $L$, and we may call it a generalized holomorphic bundle. From the ellipticity of the Lie algebroid complex for $L$ and the fact that $K$ is a module over $L$, we immediately obtain the following.

**Proposition 3.16.** The cohomology of the complex $(U^*, \overline{\partial})$, called the generalized Dolbeault cohomology $H^*_\overline{\partial}(M)$, is a finite dimensional graded module over $H^*(M, L)$ associated to any compact generalized complex manifold.

In the case of a complex structure, Equation (3.9) shows that the generalized Dolbeault cohomology coincides with the usual Dolbeault cohomology, with grading

$$H^k_\overline{\partial}(M) = \bigoplus_{p-q=k} H^p_{\overline{\partial}}(M).$$

27
A special case occurs when the canonical line bundle is holomorphically trivial, in the sense that $(K, \overline{\partial})$ is isomorphic to the trivial bundle $M \times \mathbb{C}$ together with the canonical Lie algebroid connection $d_L$. Then the Lie algebroid complex and the generalized Dolbeault complex $(U^\bullet, \overline{\partial})$ are isomorphic and hence $H^*_\overline{\partial}(M) \cong H^*(M, L)$. This holomorphic triviality of $K$ is equivalent to the existence of a nowhere-vanishing section $\rho \in C^\infty(K)$ satisfying $d_H \rho = 0$. In [18], Hitchin calls these generalized Calabi-Yau structures:

**Definition 3.17.** A generalized Calabi-Yau structure is a generalized complex structure with holomorphically trivial canonical bundle, i.e. admitting a nowhere-vanishing $d_H$-closed section $\rho \in C^\infty(K)$.

An example of a generalized Calabi-Yau structure is of course the complex structure of a Calabi-Yau manifold, which admits a holomorphic volume form $\Omega$ trivializing the canonical line bundle. On the other hand, a symplectic structure has canonical line bundle generated by the closed form $\omega$, so it too is generalized Calabi-Yau.

Assuming that the canonical bundle is trivial as a smooth line bundle, i.e. $c_1(K) = 0$, we may always choose a non-vanishing section $\rho \in C^\infty(K)$; by Theorem 3.15 integrability implies that

$$d_H \rho = \chi_\rho \cdot \rho,$$

for a uniquely determined $\chi_\rho \in C^\infty(T) = C^\infty(L^*)$. Applying (3.15), we obtain

$$0 = d_H^2 \rho = (d_L \chi_\rho) \cdot \rho - \chi_\rho \cdot (\chi_\rho \cdot \rho),$$

implying that $d_L \chi_\rho = 0$. Just as for the modular class of a Poisson structure [2.20], $\chi_\rho$ defines a class in the Lie algebroid cohomology

$$[\chi_\rho] \in H^1(M, L)$$

(3.16)

which is the obstruction to the existence of a generalized Calabi-Yau structure.

More generally, we may use standard Čech arguments to show that any generalized holomorphic line bundle $V$ is classified up to isomorphism by an element $[V] \in \mathbb{H}^1(L_{\log})$ in the first hypercohomology of the complex $L_{\log}$, given by

$$C^\infty(C^*) \xrightarrow{d_L \log} C^\infty(L^*) \xrightarrow{d_L} C^\infty(\wedge^2 L^*) \xrightarrow{d_L} \cdots.$$

**Definition 3.18.** The Picard group of isomorphism classes of rank 1 generalized holomorphic bundles, i.e. modules over $L$, is $Pic(J) = \mathbb{H}^1(L_{\log})$.

Of course this implies that $J$ is generalized Calabi-Yau if and only if $[K] = 0$ as a class in $\mathbb{H}^1(L_{\log})$. The usual exponential map induces a long exact sequence of hypercohomology groups

$$\cdots \longrightarrow H^1(M, L) \longrightarrow \mathbb{H}^1(L_{\log}) \xrightarrow{c_*} H^2(\mathbb{Z}) \longrightarrow \cdots,$$

and so we recover the observation (3.16) that when $c_1(K) = 0$ the Calabi-Yau obstruction lies in $H^1(M, L)$.

**Example 3.19.** Suppose that the complex bundle $V$ is generalized holomorphic for a complex structure $J_V$. Then the differential $D : C^\infty(V) \longrightarrow C^\infty(L^* \otimes V)$ may be decomposed according to $L = T_{0,1} \oplus T_{1,0}$ to yield

$$D = \overline{\partial}_V + \Phi,$$

where $\overline{\partial}_V : C^\infty(V) \longrightarrow C^\infty(T_{0,1}^* \otimes V)$ is a usual partial connection, $\Phi : V \longrightarrow T_{1,0} \otimes V$ is a bundle map, and $D \circ D = 0$ yields the conditions
• $\overline{\partial}_V = 0$, i.e. $V$ is a usual holomorphic bundle,
• $\overline{\partial}_V(\Phi) = 0$, i.e. $\Phi$ is holomorphic,
• $\Phi \wedge \Phi = 0$ in $\wedge^2 T_{1,0} \otimes \text{End}(V)$.

In the rank 1 case, therefore, we obtain the result

$$\text{Pic}(J) = H^1(\mathcal{O}^*) \oplus H^0(T),$$

showing that the generalized Picard group contains the usual Picard group of the complex manifold but also includes its infinitesimal automorphisms.

### 3.3 Hamiltonian symmetries

The Lie algebra $\text{sym}(\omega)$ of infinitesimal symmetries of a symplectic manifold consists of sections $X \in C^\infty(T)$ such that $L_X \omega = 0$. The Hamiltonian vector fields $\text{ham}(\omega)$ are those infinitesimal symmetries generated by smooth functions, in the sense $X = \omega^{-1}(df)$, for $f \in C^\infty(M, \mathbb{R})$. We then have the well-known sequence

$$0 \longrightarrow \text{ham}(\omega) \longrightarrow \text{sym}(\omega) \overset{\omega^{-1}}{\longrightarrow} H^1(M, \mathbb{R}) \longrightarrow 0.$$

We now give an analogous description of the symmetries of a generalized complex structure and examine the manner in which it specializes to the cases of symplectic and complex geometry.

**Definition 3.20.** An infinitesimal symmetry $v \in \text{sym}(J)$ of a generalized complex structure $J$ on the Courant algebroid $E$ is defined to be a section $v \in C^\infty(E)$ which preserves $J$ under the adjoint action, i.e. $\text{ad}_v \circ J = J \circ \text{ad}_v$, or equivalently, $[v, C^\infty(L)] \subset C^\infty(L)$.

In the presence of a generalized complex structure $J$, a real section $v \in C^\infty(E)$ may be decomposed according to the splitting $E \otimes \mathbb{C} = L \oplus \overline{L}$, yielding $v = v^{1,0} + v^{0,1}$. Clearly $[v^{1,0}, C^\infty(L)] \subset C^\infty(L)$ by the integrability of $J$. However $[v^{0,1}, C^\infty(L)] \subset C^\infty(L)$ if and only if $d_L v^{0,1} = 0$, where we use the identification $\overline{L} = L^*$. As a result we identify $\text{sym}(J) = \ker d_L \cap C^\infty(L^*)$, and the differential complex (3.10) provides the following sequence, suggesting the definition of generalized Hamiltonian symmetries:

$$C^\infty(M, \mathbb{C}) \xrightarrow{d_L} \text{sym}(J) \longrightarrow H^1(M, L) \longrightarrow 0.$$

**Definition 3.21.** An infinitesimal symmetry $v \in \text{sym}(J)$ is Hamiltonian, i.e. $v \in \text{ham}(J)$, when $v = Df$ for $f \in C^\infty(M, \mathbb{C})$, where

$$Df = d_L f + \overline{d}_L f = d(\text{Re}f) - Jd(\text{Im}f).$$

As a result we obtain the following exact sequence of complex vector spaces:

$$0 \longrightarrow \text{ham}(J) \longrightarrow \text{sym}(J) \longrightarrow H^1(M, L) \longrightarrow 0.$$

In the case of a symplectic structure, a section $X + \xi \in C^\infty(T) \oplus T^*$ preserves $J_\omega$ precisely when $d(\omega^{-1}(X) + \xi) = 0$, i.e. when $L_X \omega = 0$ and $d\xi = 0$. On the other hand, computing $Df$, we obtain

$$Df = d(\text{Re}f) + \omega^{-1}(d(\text{Im}f)),$$

showing that $X + \xi$ is Hamiltonian precisely when $X$ is Hamiltonian and $\xi$ is exact.
In the complex case, \( X + \xi \) preserves \( J \) exactly when \( \overline{\partial}(X^{1,0} + \xi^{0,1}) = 0 \), i.e. when \( X \) is a holomorphic vector field and \( \overline{\partial}\xi^{0,1} = 0 \). We also have

\[
Df = \overline{\partial}f + \partial f,
\]

showing that \( X + \xi \) is Hamiltonian exactly when \( X = 0 \) and \( \xi = \overline{\partial}f + \partial f \) for \( f \in C^\infty(M, \mathbb{C}) \).

Even for a usual complex manifold, therefore, there are nontrivial Hamiltonian symmetries \( \xi = \overline{\partial}f + \partial f \), which integrate to \( B \)-field transformations \( e^{itB} \), for \( B = \partial \overline{\partial}(f - \overline{f}) \).

### 3.4 The Poisson structure and its modular class

In this section we describe a natural Poisson structure on a generalized complex manifold which governs the behaviour of the symplectic distribution \( \Delta \) introduced in Section 3.1. A formulation of the integrability of \( J \) which will be of use is the analog of the vanishing of the Nijenhuis tensor of an almost complex structure.

**Definition 3.22.** Let \( J \) be a generalized almost complex structure. Then we define the Nijenhuis tensor \( N_J \in C^\infty(\wedge^2 E^* \otimes E) \) as follows:

\[
N_J(e_1, e_2) = [J e_1, J e_2] - J [J e_1, e_2] - J [e_1, J e_2] - [e_1, e_2]. \tag{3.17}
\]

As in the case of an almost complex structure, \( J \) is integrable if and only if \( N_J = 0 \) by the usual argument, which we omit.

The endomorphism \( J \) gives rise to an orthogonal \( S^1 \)-action on the total space of the Courant algebroid \( E \); indeed we have, for \( v \in E \) and \( t \in \mathbb{R} \),

\[
e^{it} \cdot v = e^{tJ}(v).
\]

We now show that when \( J \) is integrable, the \( S^1 \) family of almost Dirac structures obtained by applying the above action to \( T^* \) is actually integrable for all \( t \).

**Proposition 3.23.** Let \( J \) be a generalized complex structure. Then the family of almost Dirac structures

\[
D_t = e^{tJ}(T^*)
\]

is integrable for all \( t \).

**Proof.** Let \( a, b \in \mathbb{R} \). Then for \( \xi, \eta \in C^\infty(T^*) \), we use (3.17) to obtain

\[
[(a + bJ)\xi, (a + bJ)\eta] = ab([\xi, J\eta] + [J\xi, \eta]) + b^2[J\xi, J\eta] = b(a + bJ)([\xi, J\eta] + [J\xi, \eta]).
\]

Since \( ([\xi, J\eta] + [J\xi, \eta]) \) is a 1-form, we see that \( (a + bJ)T^* \) is involutive. Setting \( a = \cos t \) and \( b = \sin t \) for each \( t \), we obtain the result.

The path of Dirac structures \( D_t \) may be differentiated at \( t = 0 \) as a path in the Grassmannian of maximal isotropic subbundles of \( E \), yielding a bundle map \( P : T^* \rightarrow E/T^* = T \), given by the expression, for \( \xi, \eta \in T^* \),

\[
P(\xi, \eta) = \frac{d}{dt}D_t(\xi, \eta) = \frac{d}{dt}(e^{tJ}\xi, \eta) = (J\xi, \eta).
\]

As a map \( T^* \rightarrow T \), therefore, \( P = \pi \circ J \). Therefore we see immediately that \( \text{Im} P = \Delta \), defined in Equation \( \text{[3.5]} \). We now show that \( P \) is a Poisson structure.

**Proposition 3.24.** The bivector field \( P = \pi \circ J|_{T^*} : T^* \rightarrow T \) is Poisson.
Proof. Choose a splitting for the Courant algebroid, with curvature $H$. Then for sufficiently small $t$, the Dirac structures $D_t$ may be described as graphs of bivector fields $\beta_t : T^* \to T$. Since $D_t$ are integrable, Example 2.15 indicates that $\beta_t$ satisfy

$$[\beta_t, \beta_t] = \wedge^3 \beta_t^*(H).$$

Letting $t \to 0$, we see that the cubic term is negligible and $[P, P] = 0$, as required. \qed

**Corollary 3.25.** The distribution $\Delta = \pi(JT^*) = \mathrm{Im}P$ integrates to a generalized foliation by smooth symplectic leaves with codimension $2k$, where $k = \text{type}(J)$.

Given an isotropic splitting for the Courant algebroid, $J$ may be written as a block matrix

$$J = \begin{pmatrix} A & P \\ \sigma & -A^* \end{pmatrix},$$

so that the Poisson tensor $P$ is apparent. For a direct calculation that $P$ is Poisson, as well as more details concerning the tensors $A, \sigma$, see \cite{1,13}.

In the preceding discussion, the Poisson structure $P$ had a natural interpretation as an infinitesimal deformation of the Dirac structure $T^*$ rather than a genuine Dirac structure. We now use the tensor product of Dirac structures described in Section 2.5 to provide an alternative, more global, interpretation of $P$ as a Dirac structure in $T \oplus T^*$. In particular, Proposition 2.26 suggests the following result.

**Proposition 3.26.** Let $J$ be a generalized complex structure with $+i$ eigenbundle $L \subset E \otimes \mathbb{C}$. Then

$$L^\top \otimes \overline{L} = \Gamma_{iP/2},$$

i.e. the tensor product of $L^\top$ with $\overline{L}$ is the graph of the Poisson structure $iP/2$ in $(T \oplus T^*) \otimes \mathbb{C}$.

Proof. Let $\zeta \in T^* \otimes \mathbb{C}$, so that $\zeta - iJ\zeta \in L$, or in any splitting, using (3.18), we have $\zeta - iP\zeta + iA^*\zeta \in L$. Therefore $(\zeta - iP\zeta + iA^*\zeta)^\top = (-\zeta - iP\zeta - iA^*\zeta) \in L^\top$ and $\zeta + iP\zeta - iA^*\zeta \in \overline{L}$. Combining these using (2.24), we see that

$$iP\zeta + 2\zeta \in L^\top \otimes \overline{L},$$

and hence $\Gamma_{iP/2} \subset L^\top \otimes \overline{L}$. Since both sides are maximal isotropic subbundles, we must have equality, as required. \qed

Besides the fact that this provides an alternative proof of the fact that $P$ is Poisson, it also relates the Lie algebroids defined by $L$ and $\overline{L}$ to that defined by the Poisson structure $P$. We now observe that this implies a relation between the Calabi-Yau obstruction class and the modular class.

**Proposition 3.27.** Let $J$ be a generalized complex structure such that $c_1(K) = 0$, and let $\rho \in C^\infty(K)$ be a non-vanishing section with

$$d_H\rho = v \cdot \rho, \quad v \in C^\infty(E).$$

Then $-2\pi(Jv) = X$ is the modular vector field associated to the Poisson structure $P$ and volume form $(\rho, \overline{\rho})$.

Proof. Let $d_H\rho = v^{0,1} \cdot \rho$ for uniquely defined $v^{0,1} \in C^\infty(\overline{L})$, so that $v = v^{1,0} + v^{0,1}$ for $v^{1,0} = \overline{v^{0,1}}$. By Equation (3.19) and Proposition 2.25, we have that

$$\rho^\top \wedge \overline{\rho} = e^{\psi/2}(\rho, \overline{\rho}) = \phi.$$
Taking the exterior derivative, and using the definition (2.20) of the modular vector field, we have

\[
d\varphi = \tilde{X} \cdot \varphi = (-1)^{|\varphi|} ((dH\rho)^T \wedge \bar{\rho} + \rho^T \wedge (dH\bar{\rho}))
\]

\[
= (-1)^{|\varphi|} (v^{0,1} \cdot \bar{\rho}^T \wedge \bar{\rho} + \rho^T \wedge (v^{1,0} \cdot \bar{\rho}))
\]

\[
= -\pi (v^{0,1} - v^{1,0}) \cdot (\rho^T \wedge \bar{\rho})
\]

\[
= -i\pi (\mathcal{J}v) \cdot \varphi,
\]

showing that \( \tilde{X} = -i\pi (\mathcal{J}v) \) is the modular vector field for \( iP/2 \). Rescaling the Poisson structure, we obtain the result.

**Corollary 3.28.** The Poisson structure \( P \) associated to a generalized Calabi-Yau manifold is unimodular in the sense of Weinstein [37], i.e. it has vanishing modular class.

The map \( H^1(M,L) \to H^1(M,\Gamma P) \) of Lie algebroid cohomology groups implicit in the above result may be understood from the fact that the projection map \( T^* \otimes \mathbb{C} \to L \) obtained from the splitting \( E \otimes \mathbb{C} = L \oplus \bar{L} \), is actually a Lie algebroid morphism, when \( T^* \otimes \mathbb{C} \) is endowed with the Poisson Lie algebroid structure, as we now explain.

**Proposition 3.29.** Let \( L, P \) be the \(+i\)-eigenbundle and Poisson structure associated to a generalized complex structure. The bundle map \( a : \Gamma P \to L \) given, for any \( \xi \in T^* \otimes \mathbb{C} \), by

\[
a : \xi + P\xi \mapsto i\xi + \mathcal{J}\xi,
\]

(3.20)

is a Lie algebroid homomorphism.

**Proof.** The map \( a \) commutes with the projections to the tangent bundle, since \( P = \pi \circ \mathcal{J}|_{T^*} \).

Given 1-forms \( \xi, \eta \), we have

\[
[a(\xi + P\xi), a(\eta + P\eta)] = [\xi, \mathcal{J}\eta] + [\mathcal{J}\xi, \eta] + [\mathcal{J}\xi, \mathcal{J}\eta]
\]

\[
= i(\xi, P\eta) + [P\xi, \eta]) + \mathcal{J}(\xi, P\eta) + [P\xi, \eta]
\]

\[
= a(\xi + P\xi, \eta + P\eta),
\]

as required. \( \Box \)

As a final example of the relationship between a generalized complex structure and its associated Poisson structure, we use the above Lie algebroid homomorphism to relate the infinitesimal symmetries of each structure.

**Proposition 3.30.** If \( \mathcal{J} \) is a generalized complex structure and \( P \) its associated Poisson structure, then the maps \( E \to T \) defined by \( v \mapsto \pi(v) \) and \( v \mapsto \pi(\mathcal{J}v) \) both induce homomorphisms

\[
0 \to \text{ham}(\mathcal{J}) \to \text{sym}(\mathcal{J}) \to H^1(M, L) \to 0.
\]

\[
0 \to \text{ham}(P) \to \text{sym}(P) \to H^1(M, \Gamma P) \to 0
\]

from the infinitesimal symmetries of \( \mathcal{J} \) to the infinitesimal symmetries of \( P \).

**Proof.** Identifying \( \text{sym}(\mathcal{J}) = \ker d_L \cap C^\infty(L^*) \), we see from Proposition 3.29 that \( a^* : L^* \to \Gamma P \otimes \mathbb{C} \) is a morphism of differential complexes. Identifying \( \Gamma P \cong T \), and taking real and imaginary parts, we obtain morphisms \( v \mapsto \pi(v), v \mapsto \pi(\mathcal{J}v) \) as required. \( \Box \)
3.5 Interpolation

As we saw in section 3.1 symplectic structures have type 0 while complex structures have type $n$ on a manifold of real dimension $2n$. Hence complex and symplectic structures have the same parity in real dimension $4k$. We now show that it is possible to interpolate smoothly between a complex structure and a symplectic structure through integrable generalized complex structures when $M$ is hyperkähler (or, more generally, holomorphic symplectic). This example is also described in [18], using spinors.

Let $M$ be a real manifold of dimension $4k$ with complex structure $I$ and holomorphic symplectic structure $\sigma = \omega_j + i\omega_K$, so that $\sigma$ is a nondegenerate closed $(2,0)$-form. Since $\omega_j$ is of type $(2,0) + (0,2)$, we have $\omega_j I = I^* \omega_j$, and hence

$$
\begin{pmatrix}
\omega_j & -\omega_j^{-1} \\
-\omega_j^{-1} & I^*
\end{pmatrix}
\begin{pmatrix}
-I \\
I^*
\end{pmatrix}
= 
-\begin{pmatrix}
-I \\
I^*
\end{pmatrix}
\begin{pmatrix}
\omega_j & -\omega_j^{-1} \\
-\omega_j^{-1} & I^*
\end{pmatrix},
$$

that is, the generalized complex structures $J_\omega$ and $J_t$ anticommute. Hence we may form the one-parameter family of generalized almost complex structures

$$
J_t = (\sin t) J_1 + (\cos t) J_\omega, \quad t \in [0, \pi].
$$

Clearly $J_t$ is a generalized almost complex structure; we now check that it is integrable.

**Proposition 3.31.** Let $M$ be a holomorphic symplectic manifold as above. Then the generalized almost complex structure $J_t = (\sin t) J_1 + (\cos t) J_\omega$, is integrable $\forall t \in [0, \pi]$. Therefore it is a family of generalized complex structures interpolating between a symplectic structure and a complex structure.

**Proof.** Let $B = (\tan t) \omega_K$, a closed 2-form which is well defined $\forall t \in [0, \pi]$. Noting that $\omega_K I = I^* \omega_K = \omega_j$, we obtain the following expression:

$$
e^B J_t e^{-B} = 
\begin{pmatrix}
0 & -((\sec t) \omega_j)^{-1} \\
(\sec t) \omega_j & 0
\end{pmatrix}.
$$

We conclude from this that for all $t \in [0, \pi/2)$, $J_t$ is a B-field transform of the symplectic structure determined by $(\sec t) \omega_j$, and is therefore integrable as a generalized complex structure; at $t = \frac{\pi}{2}$, $J_t$ is purely complex, and is integrable by assumption, completing the proof. \(\square\)

4 Local structure: the generalized Darboux theorem

The Newlander-Nirenberg theorem informs us that an integrable complex structure on a $2n$-manifold is locally equivalent, via a diffeomorphism, to $\mathbb{C}^n$. Similarly, the Darboux theorem states that a symplectic structure on a $2n$-manifold is locally equivalent, via a diffeomorphism, to the standard symplectic structure $(\mathbb{R}^{2n}, \omega_0)$, where in coordinates $(x_1, \ldots, x_n, p_1, \ldots, p_n)$,

$$\omega_0 = dx_1 \wedge dp_1 + \cdots + dx_n \wedge dp_n.$$

In this section we prove an analogous theorem for generalized complex manifolds, describing a local normal form for a regular neighbourhood of a generalized complex manifold.

**Definition 4.1.** A point $p \in M$ in a generalized complex manifold is called regular when the Poisson structure $P$ is regular at $p$, i.e. type$(\mathcal{J})$ is locally constant at $p$.

By Corollary 3.29 a generalized complex structure defines, in a regular neighbourhood $U$, a foliation $\mathcal{F}$ by symplectic leaves of codimension $2k = 2$ type$(\mathcal{J})$, integrating the distribution $\Delta = \pi(\mathcal{J} T^*)$. The complex structure transverse to $\Delta$ described in Section 3.1 defines an integrable complex structure on the leaf space $U/\mathcal{F}$ as we now describe.
Proposition 4.2. The leaf space $U/F$ of a regular neighbourhood of a generalized complex manifold inherits a canonical complex structure.

Proof. Let $L \subset E$ be the $+i$-eigenbundle of $\mathcal{J}$ and let $D = \pi_{T \otimes \mathbb{C}}(L)$ be its projection to the complex tangent bundle, which is smooth in a regular neighbourhood since $\text{type}(\mathcal{J}) = \dim L \cap (T^* \otimes \mathbb{C})$. Then $E \otimes \mathbb{C} = L \oplus L$ implies that $T \otimes \mathbb{C} = D + \mathcal{D}$, while $D \cap \mathcal{D} = \Delta \otimes \mathbb{C}$. Since the projection $\pi$ is bracket-preserving, we see that $D$ is an integrable distribution, hence $[\Delta, D] \subset D$. This implies that $D$ descends to an integrable subbundle $D' \subset T(U/F) \otimes \mathbb{C}$ satisfying $D' \cap \mathcal{D}' = \{0\}$, hence defining an integrable complex structure on $U/F$, as required. This coincides with the complex structure induced by $\mathcal{J}$ on $E/(T^* + J T^*) = T/\Delta$. \hfill \Box

We now prove that near a regular point, the symplectic structure on the leaves, together with the complex structure on the leaf space, completely characterize the generalized complex structure.

Theorem 4.3 (Generalized Darboux theorem). Any regular point of type $k$ in a generalized complex manifold has a neighbourhood which is equivalent, via a diffeomorphism and a choice of splitting of the Courant algebroid $E$, to the product of an open set in $\mathbb{C}^k$ with an open set in the standard symplectic space $(\mathbb{R}^{2n-2k}, \omega_0)$.

Proof. First choose a local isotropic splitting for the Courant algebroid so that it is isomorphic, within the neighbourhood $U$, to $(T \oplus T^*, [\cdot, \cdot])$; this is always possible as long as $H^3(U, \mathbb{R}) = 0$. Proposition 4.2 then guarantees the existence of holomorphic coordinates $(z_1, \ldots, z_k)$ transverse to the symplectic foliation in the regular neighbourhood; then a local generator for the canonical bundle may be chosen, as in (3.6), to be

$$\rho = e^{B+i\omega} \Omega,$$

where $\Omega = dz_1 \wedge \cdots \wedge dz_k$ and $B, \omega$ are real 2-forms such that

$$\omega^{n-k} \wedge \Omega \wedge \overline{\Omega} \neq 0.$$

Integrability then implies, via Proposition 2.11, that

$$d \rho = e^{B+i\omega} d(B+i\omega) \wedge \Omega = 0. \quad (4.1)$$

The symplectic form $\omega|_\Delta$ along the leaves derives from the Poisson structure $P$, and hence by Weinstein’s normal form for regular Poisson structures [36], we can find a leaf-preserving local diffeomorphism $\varphi : \mathbb{R}^{2n-2k} \times \mathbb{C}^k \longrightarrow U$ such that

$$\varphi^* \omega|_{\mathbb{R}^{2n-2k} \times \{pt\}} = \omega_0 = dx_1 \wedge dp_1 + \cdots + dx_{n-k} \wedge dp_{n-k}. $$

For convenience, let $K = \mathbb{R}^{2n-2k}$ and $N = \mathbb{C}^k$, so that differential forms now have tri-degree $(p, q, r)$ for components in $\wedge^p K^* \otimes \wedge^q N^*_{1,0} \otimes \wedge^r N_{0,1}$. Furthermore, the exterior derivative decomposes into a sum of three operators

$$d = d_{\Delta} + \partial + \overline{\partial},$$

each of degree 1 in the respective component of the tri-grading. While $\Omega$ is purely of type $(0, k, 0)$, the complex 2-form $A = \varphi^* B + i\varphi^* \omega$ decomposes into six components:

$$A^{200} \quad A^{110} \quad A^{101} \quad A^{020} \quad A^{011} \quad A^{002}$$

34
Note that only the components $A^{200}, A^{101}, A^{002}$ act nontrivially on $\Omega$ in the expression $e^{A} \Omega$. Hence we are free to modify the other three components at will. Also, note that the imaginary part of $A^{200}$ is simply $\omega_0$, so that $d(A^{200} - \overline{A^{200}}) = 0$, since $\omega_0$ is in constant Darboux form. From (4.1), we have $d(B + i\omega) \wedge \Omega = 0$, giving the following four equations:

\begin{align*}
\overline{\partial} A^{002} &= 0 \quad (4.2) \\
\overline{\partial} A^{101} + d\Delta A^{002} &= 0 \quad (4.3) \\
\overline{\partial} A^{200} + d\Delta A^{101} &= 0 \quad (4.4) \\
d\Delta A^{200} &= 0. \quad (4.5)
\end{align*}

We will now endeavour to modify $A$ so that $\varphi^* \rho = e^{A} \Omega$ is unchanged but $A$ is replaced with $\tilde{A} = \tilde{B} + \frac{1}{2}(A^{200} - \overline{A^{200}})$, where $\tilde{B}$ is a real closed 2-form. This would demonstrate that $\varphi^* \rho = e^{\tilde{B} + i\omega_0} \Omega$, i.e. $\rho$ is equivalent, via a diffeomorphism and $B$-field symmetry, to the product of a symplectic with a complex structure. The $B$-field transform is simply a change in the original splitting for $(T \oplus T^*, [\cdot, \cdot])$.

In order to preserve $\varphi^* \rho$, the most general form for $\tilde{B}$ is

$$\tilde{B} = \frac{1}{2}(A^{200} + \overline{A^{200}}) + A^{101} + \overline{A^{101}} + A^{002} + \overline{A^{002}} + C,$$

where $C$ is a real 2-form of type (011). Then clearly $\varphi^* \rho = e^{\tilde{B} + i\omega_0} \Omega$. Requiring that $d\tilde{B} = 0$ imposes two constraint equations:

\begin{align*}
(d\tilde{B})^{012} &= \partial A^{002} + \overline{\partial} C = 0. \quad (4.6) \\
(d\tilde{B})^{111} &= \partial A^{101} + \overline{\partial} A^{101} + d\Delta C = 0 \quad (4.7)
\end{align*}

The question then becomes whether we can find a real (011)-form $C$ such that these equations are satisfied. The following are all local arguments, making repeated use of the Dolbeault lemma.

- From equation (4.2) we obtain that $A^{002} = \overline{\partial} \alpha$ for some (001)-form $\alpha$. Then condition (4.6) is equivalent to $\overline{\partial}(C - \partial \alpha) = 0$, whose general solution is

$$C = \partial\alpha + \overline{\partial}\alpha + i\partial\overline{\partial}\chi$$

for any real function $\chi$. We must now check that it is possible to choose $\chi$ so that the second condition (4.7) is satisfied by this $C$.

- From equation (4.3) we obtain that $\overline{\partial}(A^{101} - d\Delta \alpha) = 0$, implying that $A^{101} = d\Delta \alpha + \overline{\partial} \beta$ for some (100)-form $\beta$. Condition (4.7) then is equivalent to the fact that

$$-i d\Delta \partial\overline{\partial}\chi = \partial\overline{\partial}(\beta - \overline{\beta}),$$

which can be solved (for the unknown $\chi$) if and only if the right hand side is $d\Delta$-closed. From equation (4.4) we see that $\overline{\partial}(A^{200} - d\Delta \beta) = 0$, showing that $A^{200} = d\Delta \beta + \delta$, where $\delta$ is a $\overline{\partial}$-closed (200)-form. Hence

$$d\Delta \partial\overline{\partial}(\beta - \overline{\beta}) = \partial\overline{\partial}(A^{200} - \overline{A^{200}}),$$

and the right hand side vanishes precisely because $A^{200} - \overline{A^{200}} = 2\omega_0$, which is closed. Hence $\chi$ may be chosen to satisfy condition (4.7), and so we obtain a closed 2-form $\tilde{B}$. \qed
4.1 Type jumping

While Theorem 4.3 fully characterizes generalized complex structures in regular neighbourhoods, it remains an essential feature of the geometry that the type of the structure may vary throughout the manifold. The most generic type is zero, when there are only symplectic directions and the Poisson structure $P$ has maximal rank. The type may jump up along closed subsets, has maximal value $n = \frac{1}{2} \dim M$, and has fixed parity throughout the manifold. We now present a simple example of a generalized complex structure on $\mathbb{R}^4$ which is of symplectic type ($k = 0$) outside a codimension 2 hypersurface and jumps up to complex type ($k = 2$) along the hypersurface.

Consider the differential form

$$\rho = z_1 + dz_1 \wedge dz_2, \quad (4.8)$$

where $z_1, z_2$ are the standard coordinates on $\mathbb{C}^2 \cong \mathbb{R}^4$. Along $z_1 = 0$, we have $\rho = dz_1 \wedge dz_2$ and so it generates the pure spinor line corresponding to the standard complex structure. Whenever $z_1 \neq 0$, $\rho$ may be rewritten as follows:

$$\rho = z_1 e^{\frac{dz_1 \wedge dz_2}{z_1}}.$$

Therefore away from $z_1 = 0$, $\rho$ generates the canonical line bundle of the $B$-field transform of the symplectic form $\omega$, where

$$B + i \omega = z_1^{-1} dz_1 \wedge dz_2.$$

Hence, algebraically the form $\rho$ defines a generalized almost complex structure which is generically of type 0 but jumps to type 2 along $z_1 = 0$.

To verify the integrability of this structure, we take the exterior derivative:

$$d\rho = dz_1 = i - \partial_{z_2} (z_1 + dz_1 \wedge dz_2) = (-\partial_{z_2}) \cdot \rho,$$

showing that $\rho$ indeed satisfies the integrability condition of Theorem 3.15 and defines a generalized complex structure on all of $\mathbb{R}^4$. In this case it is easy to see that although the canonical line bundle is topologically trivial, it does not admit a closed, nowhere-vanishing section. Hence the generalized complex structure is not generalized Calabi-Yau.

In the next chapter we will produce more general examples of the jumping phenomenon, and on compact manifolds as well. However we indicate here that the simple example above was used in [8] to produce, via a surgery on a symplectic 4-manifold, an example of a compact, simply-connected generalized complex 4-manifold which admits neither complex nor symplectic structures.

5 Deformation theory

In the deformation theory of complex manifolds developed by Kodaira, Spencer, and Kuranishi, one begins with a compact complex manifold $(M, J)$ with holomorphic tangent bundle $T$, and constructs an analytic subvariety $Z \subset H^1(M, T)$ (containing 0) which is the base space of a family of deformations $\mathcal{M} = \{\epsilon(z) : z \in Z, \epsilon(0) = 0\}$ of the original complex structure $J$. This family is locally complete (also called miniversal), in the sense that any family of deformations of $J$ can be obtained, up to equivalence, by pulling $\mathcal{M}$ back by a map $f$ to $Z$, as long as the family is restricted to a sufficiently small open set in its base.

The subvariety $Z \subset H^1(M, T)$ is defined as the zero set of a holomorphic map $\Phi : H^1(M, T) \to H^2(M, T)$, and so the base of the miniversal family is certainly smooth when this obstruction map vanishes.

In this section we extend these results to the generalized complex setting, following the method of Kuranishi [27]. In particular, we construct, for any generalized complex manifold,
a locally complete family of deformations. We then proceed to produce new examples of generalized complex structures by deforming known ones.

5.1 Lie bialgebroids and the deformation complex

The generalized complex structure \( J \) on the exact Courant algebroid \( E \) is determined by its +i-eigenbundle \( L \subset E \otimes \mathbb{C} \) which is isotropic, satisfies \( L \cap \overline{L} = \{0\} \), and is Courant involutive. Recall that since \( E \otimes \mathbb{C} = L \oplus \overline{L} \), we use the natural metric \( \langle \cdot, \cdot \rangle \) to identify \( L \) with \( L^* \).

To deform \( J \) we will vary \( L \) in the Grassmannian of maximal isotropics. Any maximal isotropic having zero intersection with \( \overline{L} \) (this is an open set containing \( L \)) can be uniquely described as the graph of a homomorphism \( \epsilon : L \rightarrow \overline{L} \) satisfying \( \langle \epsilon X, Y \rangle + \langle X, \epsilon Y \rangle = 0 \) \( \forall X, Y \in C^\infty(L) \), or equivalently \( \epsilon \in C^\infty(\wedge^2 L^*) \). Therefore the new isotropic is given by

\[
L_\epsilon = (1 + \epsilon)L = \{u + i_\epsilon \epsilon : u \in L\}.
\]

As the deformed \( J \) is to remain real, we must have \( \overline{L}_\epsilon = (1 + \epsilon)L \). Now we observe that \( L_\epsilon \) has zero intersection with its conjugate if and only if the endomorphism we have described on \( L \oplus L^* \), namely

\[
A_\epsilon = \begin{pmatrix} 1 & \epsilon \\ \epsilon & 1 \end{pmatrix},
\]

is invertible; this is the case for \( \epsilon \) in an open set around zero.

So, providing \( \epsilon \) is small enough, \( J_\epsilon = A_\epsilon J A_\epsilon^{-1} \) is a new generalized almost complex structure, and all nearby almost structures are obtained in this way. Note that while \( A_\epsilon \) itself is not an orthogonal transformation, of course \( J_\epsilon \) is.

To describe the condition on \( \epsilon \in C^\infty(\wedge^2 L^*) \) which guarantees that \( J_\epsilon \) is integrable, we observe the following. Since \( L^* = \overline{L} \), we have not only an elliptic differential complex (by Proposition 3.11)

\[
(C^\infty(\wedge^* L^*), d_L),
\]

but also a Lie algebroid structure on \( L^* \) coming from the Courant bracket on \( \overline{L} \). In fact, by a theorem of Liu-Weinstein-Xu [28], the differential is a derivation of the bracket and we obtain the structure of a Lie bialgebroid in the sense of Mackenzie-Xu [29], also known as a differential Gerstenhaber algebra.

**Theorem 5.1 (28, Theorem 2.6).** Let \( E \) be an exact Courant algebroid and \( E = L \oplus L' \) for Dirac structures \( L, L' \). Then \( L' = L^* \) using the inner product, and the dual pair of Lie algebroids \((L, L^*)\) defines a Lie bialgebroid, i.e.

\[
d_L[a, b] = [d_L a, b] + [a, d_L b],
\]

for \( a, b \in C^\infty(L^*) \), where \([\cdot, \cdot]\) is extended in the Schouten sense to \( C^\infty(\wedge^* L^*). \) Therefore the data

\[
(C^\infty(\wedge^* L^*), d_L, [\cdot, \cdot])
\]

define a differential Gerstenhaber algebra.

Interpolating between the examples 2.14 and 2.15 Liu-Weinstein-Xu [28] also prove that, under the assumptions of the previous theorem, the graph \( L_\epsilon \) of a section \( \epsilon \in C^\infty(\wedge^2 L^*) \) defines an integrable Dirac structure if and only if it satisfies the Maurer-Cartan equation.

**Theorem 5.2 (28, Theorem 6.1).** The almost Dirac structure \( L_\epsilon \), for \( \epsilon \in C^\infty(\wedge^2 L^*) \), is integrable if and only if \( \epsilon \) satisfies the Maurer-Cartan equation

\[
d_L \epsilon + \frac{1}{2} [\epsilon, \epsilon] = 0.
\]

Here \( d_L : C^\infty(\wedge^k L^*) \rightarrow C^\infty(\wedge^{k+1} L^*) \) and \([\cdot, \cdot]\) is the Lie algebroid bracket on \( L^* \).
Therefore we conclude that the deformed generalized almost complex structure $J_u$ is integrable if and only if $\epsilon$ satisfies the Maurer-Cartan equation (5.2). We may finally define a smooth family of deformations of the generalized complex structure $J$. We are only interested in “small” deformations.

**Definition 5.3.** Let $U$ be an open disk containing the origin of a finite-dimensional vector space. A smooth family of deformations of $J$ over $U$ is a family of sections $\epsilon(u) \in C^\infty(\wedge^2 L^*)$, smoothly varying in $u \in U$, with $\epsilon(0) = 0$, such that (5.1) is invertible, and satisfying the Maurer-Cartan equation (5.2) for each $u \in U$. Two such families $\epsilon_1(u), \epsilon_2(u)$ are equivalent if $F_u(L_{\epsilon_1}(u)) = L_{\epsilon_2}(u)$ for all $u \in U$, where $F_u$ is a smooth family of Courant automorphisms with $F_0 = \text{id}$.

The space of solutions to (5.2) is infinite-dimensional, however due to the action of the group of Courant automorphisms we are able, as in the case of complex manifolds, to take a time-independent derivations $\text{ad}(\cdot)$ are families of exact Courant automorphisms in the sense of Definition 2.7, generated by $v$-exact Courant automorphisms $\phi$ for another section $v \in C^\infty(E)$, $u \in U$. A similar situation occurs in the case of deformations of complex structure.

Suppose $v \in C^\infty(E)$ and let $F^1_v$ denote its time-1 flow defined by (2.10), so that in a splitting for $E$ with curvature $H$, we have $v = X + \xi$ and by (2.11),

$$F^1_v(\cdot) = \varphi^1_*(e^B_{\cdot}), \quad B_1 = \int_0^1 \varphi_s^*(iXH + d\xi) \, ds,$$  \hspace{1cm} (5.3)

where $\varphi^i_*$ is the flow of the vector field $X$. The Courant isomorphism $F^1_v$ acts on generalized complex structures, taking a given deformation $L_\epsilon$ to $F^1_v(L_\epsilon)$. If $v$ has sufficiently small 1-jet, then $F^1_v(L_\epsilon)$ may be expressed as $L_{\epsilon'}$ for another section $\epsilon' \in C^\infty(\wedge^2 L^*)$, and we denote it $F^1_v(\epsilon) := \epsilon'$. We now determine an approximate formula for $F^1_v(\epsilon)$ in terms of $(\epsilon, v)$.

**Proposition 5.4.** Let $J$ be a generalized complex structure with $+i$-eigenbundle $L \subset E \otimes \mathbb{C}$, and let $\epsilon \in C^\infty(\wedge^2 L^*)$ be such that (5.1) is invertible. Then for $v \in C^\infty(E)$ with sufficiently small 1-jet, the time-1 flow $F^1_v(\cdot)$ satisfies

$$F^1_v(\epsilon) = \epsilon + dLv^{0,1} + R(\epsilon, v),$$ \hspace{1cm} (5.4)

where $v = v^{1,0} + v^{0,1}$ according to the splitting $L \oplus L^*$, and $R$ satisfies

$$R(\epsilon, v, t) = t^2 R(\epsilon, v, t),$$

where $R(\epsilon, x + \xi, t)$ is smooth in $t$ for small $t$.

**Proof.** Define $\epsilon(s, t)$ for $s, t \in \mathbb{R}$ by

$$\epsilon(s, t) = F^1_{tv}(se),$$ \hspace{1cm} (5.5)

so that $\epsilon = \epsilon(1, 1)$ and $\epsilon(0) = 0$. We first compute the derivatives of (5.5) at $s = t = 0$. The derivative in $s$ is easily computed:

$$\left. \frac{\partial \epsilon(s, t)}{\partial s} \right|_{(0,0)} = \frac{\partial (se)}{\partial s} = \epsilon.$$

The derivative in $t$ may be computed using the property of flows that $F^1_{tv} = F^1_v$, together with the fact that the flow $F^1_v$ is generated by the adjoint action $\text{ad}(\cdot)$ of $v$ on the Courant algebroid. Using the properties of the Courant bracket, we obtain, for $y, z \in C^\infty(L)$,

$$\left. \frac{\partial \epsilon(s, t)}{\partial t} \right|_{(0,0)} (y, z) = \left. \frac{\partial F^1_v(\epsilon)}{\partial t} \right|_{(0,0)} (y, z) = ([v, y], z) = dLv^{0,1}(y, z).$$
By Taylor’s theorem we obtain

\[ F^1_{tv}(st) = se + t\partial Lv^{0,1} + r(s,t,\epsilon, v), \]

where \( r \) is smooth of order \( O(s^2, st, t^2) \) at zero. Setting \( R(\epsilon, v) = r(1, 1, \epsilon, v) \), we obtain the result, since clearly \( r(1, 1, t\epsilon, tv) = r(t, t, \epsilon, v) \) is of order \( O(t^2) \).

Whereas the Maurer-Cartan equation (5.2) indicates that, infinitesimally, deformations of generalized complex structure lie in \( \ker d_L \subset \mathcal{C}_\infty(\wedge^2 L^*) \), the previous Proposition shows us that, infinitesimally, deformations which differ by sections which lie in the image of \( d_L \) are equivalent. Hence we expect the tangent space to the moduli space to lie in the Lie algebroid cohomology \( H^2(M, L) \), which by ellipticity is finite-dimensional for \( M \) compact. We now develop the Hodge theory required to prove this assertion.

We follow the usual treatment of Hodge theory as described in [38]. Choose a Hermitian metric on the complex Lie algebroid \( L \) and let \( |\varphi|_k \) be the \( L^2 \) Sobolev norm on sections \( \varphi \in C^\infty(\wedge^p L^*) \) induced by the metric. We then have the elliptic, self-adjoint Laplacian

\[ \Delta_L = d_Ld^*_L + d^*_Ld_L. \]

Let \( \mathcal{H}^p \) be the space of \( \Delta_L \)-harmonic forms, which is isomorphic to \( H^p(M, L) \) by the standard argument, and let \( H \) be the orthogonal projection of \( C^\infty(\wedge^p L) \) onto the closed subspace \( \mathcal{H}^p \). Also, let \( G \) be the Green smoothing operator quasi-inverse to \( \Delta_L \), i.e. \( G\Delta + H = \text{Id} \) and

\[ G : L^2_k \to L^2_{k+2}. \]

We will find it useful, as Kuranishi did, to define the once-smoothing operator

\[ Q = d^*_LG : L^2_k \to L^2_{k+1}, \]

which then satisfies

\[ \text{Id} = H + d_LQ + Qd_L, \quad Q^2 = d^*_LQ = Qd^*_L = HQ = QH = 0. \]

We now have the algebraic and analytical tools required to prove a direct analog of Kuranishi’s theorem for generalized complex manifolds.

### 5.2 The deformation theorem

**Theorem 5.5.** Let \((M, J)\) be a compact generalized complex manifold. There exists an open neighbourhood \( U \subset H^2(M, L) \) containing zero, a smooth family \( \bar{\mathcal{M}} = \{\epsilon(u) : u \in U, \epsilon(0) = 0\} \) of generalized almost complex deformations of \( J \), and an analytic obstruction map \( \Phi : U \to H^3(M, L) \) with \( \Phi(0) = 0 \) and \( d\Phi(0) = 0 \), such that the deformations in the sub-family \( \mathcal{M} = \{\epsilon(z) : z \in Z = \Phi^{-1}(0)\} \) are precisely the integrable ones. Furthermore, any sufficiently small deformation \( \epsilon \) of \( J \) is equivalent to at least one member of the family \( \mathcal{M} \). In the case that the obstruction map vanishes, \( \mathcal{M} \) is a smooth locally complete family.

**Proof.** The proof is divided into two parts: first, we construct a smooth family \( \bar{\mathcal{M}} \), and show it contains the family of integrable deformations \( \mathcal{M} \) defined by the map \( \Phi \); second, we describe its miniversality property. We follow the paper of Kuranishi [27] closely, where more details can be found.

**Part 1:** For sufficiently large \( k \), \( L^2_k(M, \mathbb{R}) \) is a Banach algebra (see [32]), and the map \( f : \epsilon \mapsto \epsilon + \frac{1}{2}Q[\epsilon, \epsilon] \) extends to a smooth map

\[ f : L^2_k(\wedge^2 L^*) \to L^2_k(\wedge^2 L^*), \]
whose derivative at the origin is the identity mapping. By the inverse function theorem, $f^{-1}$ maps a neighbourhood of the origin in $L^2_k(\wedge^2 L^*)$ smoothly and bijectively to another neighbourhood of the origin. Hence, for sufficiently small $\delta > 0$, the finite-dimensional subset of harmonic sections,

$$U = \{ u \in H^2 < L^2_k(\wedge^2 L^*) : |u|_k < \delta \},$$

defines a family of sections as follows:

$$\tilde{M} = \{ \epsilon(u) = f^{-1}(u) : u \in U \},$$

where $\epsilon(u)$ depends smoothly (in fact, holomorphically) on $u$, and satisfies $f(\epsilon(u)) = u$. Applying the Laplacian to this equation, we obtain

$$\Delta_L \epsilon(u) + \frac{1}{2} d_L^* [\epsilon(u), \epsilon(u)] = 0.$$ 

This is a quasi-linear elliptic PDE, and by a result of Morrey [30], we conclude that the solutions $\epsilon(u)$ of this equation are actually smooth, i.e.

$$\epsilon(u) \in C^\infty(\wedge^2 L^*).$$

Hence we have constructed a smooth family of generalized almost complex deformations of $\mathcal{J}$, over an open set $U \subset H^2 \cong H^2(M, L)$.

We now ask which of these deformations satisfy the Maurer-Cartan equation (5.2). By definition of $\epsilon(u)$, and using (5.6), we obtain

$$d_L \epsilon(u) + \frac{1}{2} [\epsilon(u), \epsilon(u)] = -\frac{1}{2} d_L Q[\epsilon(u), \epsilon(u)] + \frac{1}{2} [\epsilon(u), \epsilon(u)]
= \frac{1}{2} (Q d_L + H)[\epsilon(u), \epsilon(u)].$$

Since the images of $Q$ and $H$ are $L^2$-orthogonal, we see that $\epsilon(u)$ is integrable if and only if $H[\epsilon(u), \epsilon(u)] = Q d_L[\epsilon(u), \epsilon(u)] = 0$. We now refer to the argument of Kuranishi [27] which, using the compatibility between $[\cdot, \cdot]$ and $d_L$, shows that $Q d_L[\epsilon(u), \epsilon(u)]$ vanishes when $H[\epsilon(u), \epsilon(u)]$ does.

Hence, $\epsilon(u)$ is integrable precisely when $u$ lies in the vanishing set of the analytic mapping $\Phi : U \to H^2_L(M)$ defined by

$$\Phi(u) = H[\epsilon(u), \epsilon(u)].$$

(5.7)

Note furthermore that $\Phi(0) = d\Phi(0) = 0$.

**Part II:** For the second part of the proof, we give an alternative characterisation of the family $\mathcal{M}$. We claim that $\mathcal{M}$ is actually a neighbourhood around zero in the set

$$\mathcal{M}' = \{ \epsilon \in C^\infty(\wedge^2 L^*) : d_L \epsilon + \frac{1}{2} [\epsilon, \epsilon] = 0, \quad d_L^* \epsilon = 0 \}. $$

To show this, let $\epsilon(u) \in \mathcal{M}$. Then since $\epsilon(u) = u - \frac{1}{2} Q[\epsilon(u), \epsilon(u)]$ and $d_L^* Q = 0$, we see that $d_L^* \epsilon(u) = 0$, showing that $\mathcal{M} \subset \mathcal{M}'$. Conversely, let $\epsilon \in \mathcal{M}'$. Then since $d_L^* \epsilon = 0$, applying $d_L^*$ to the equation $d_L \epsilon + \frac{1}{2} [\epsilon, \epsilon] = 0$ we obtain $\Delta_L \epsilon + \frac{1}{2} d_L^* [\epsilon, \epsilon] = 0$, and applying Green’s operator we see that $\epsilon + \frac{1}{2} Q[\epsilon, \epsilon] = H \epsilon$, i.e. $F(\epsilon) = H \epsilon \in H^2$. Proving that a small open set in $\mathcal{M}'$ is contained in $\mathcal{M}$, completing the argument.

We now show that every sufficiently small deformation of the generalized complex structure is equivalent to one in our finite-dimensional family $\mathcal{M}$. Let $P \subset C^\infty(L^*)$ be the $L^2$ orthogonal complement of $\ker d_L \subset C^\infty(L^*)$, or in other words, sections in the image of $d_L^*$. We show that there exist neighbourhoods of the origin $V \subset C^\infty(\wedge^2 L^*)$ and $W \subset P$ such that for any $\epsilon \in V$ there is a unique $v \in C^\infty(E)$ such that $v_{\epsilon, \cdot}^0 \in W$ and the time-1 flow $F^1_\epsilon$ satisfies

$$d_L^* F^1_\epsilon (\epsilon) = 0.$$  

(5.8)
This would imply that any sufficiently small solution to \( d_L \epsilon + \frac{1}{2} [\epsilon, \epsilon] = 0 \) is equivalent to another solution \( \epsilon' \) such that \( d_L^* \epsilon' = 0 \), i.e., a solution in \( \mathcal{M}' = \mathcal{M} \). Extended to smooth families, this result would prove local completeness.

We see from (5.4) that (5.8) holds if and only if

\[
d_L^* \epsilon + d_L^* d_L \nu^{0,1} + d_L^* R(\epsilon, \nu) = 0.
\]

Assuming \( \nu^{0,1} \in P \), we see that \( d_L^* \nu^{0,1} = H \nu^{0,1} = 0 \), so that

\[
d_L^* \epsilon + \Delta_L \nu^{0,1} + d_L^* R(\epsilon, \nu) = 0. \tag{5.9}
\]

Applying the Green operator \( G \), we obtain

\[
\nu^{0,1} + Q \epsilon + Q R(\epsilon, \nu) = 0. \tag{5.10}
\]

By the definition (5.4) of \( R(\epsilon, \nu) \), the map

\[
F: (\epsilon, \nu^{0,1}) \mapsto \nu^{0,1} + Q \epsilon + Q R(\epsilon, \nu)
\]

is continuous from a neighbourhood of the origin \( V_0 \times W_0 \) in \( C^\infty(\wedge^2 L^*) \times P \) to \( P \), where all spaces are endowed with the \( L^2_\mathbb{R} \) norm, \( k \) sufficiently large. Also, the derivative of \( F \) with respect to \( \nu^{0,1} \) (at 0) is the identity map. Therefore by the implicit function theorem, there are neighbourhoods \( V \subset V_0, W_1 \subset W_0 \) such that given \( \epsilon \in V \), equation (5.10), i.e., \( F = 0 \), is satisfied for a unique \( \nu^{0,1} \in W_1 \), and which depends smoothly on \( \epsilon \in V \). Furthermore, since \( \epsilon \in V \) is itself smooth, the unique solution \( \nu \) satisfies the quasi-linear elliptic PDE (5.9), implying that \( \nu \) is smooth as well, hence \( \nu^{0,1} \) lies in the neighbourhood \( W = W_1 \cap P \). Therefore we have shown that every sufficiently small deformation of the generalized complex structure is equivalent to one in our finite-dimensional family \( \mathcal{M} \).

If the obstruction map \( \Phi \) vanishes, so that \( \mathcal{M} \) is a smooth family, then given any other smooth family \( \mathcal{M}_s = \{ \epsilon(s) : s \in S, \epsilon(s_0) = 0 \} \) with basepoint \( s_0 \in S \), the above argument provides, for \( s \) in some neighbourhood \( T \) of \( s_0 \), a smooth family of sections \( \epsilon(s) \in C^\infty(E) \) whose time-1 flow takes each \( \epsilon(s) \) to \( \epsilon(f(s)) \), \( f(s) \in U \subset H^2(M, L) \). This defines a smooth map \( f : T \to U \), \( f(s_0) = 0 \), such that \( f^* \mathcal{M} = \mathcal{M}_s \). Thus we establish that \( \mathcal{M} \) is a locally complete family of deformations.

**Remark.** The natural complex structure on \( H^2(M, L) \) and on the vanishing set of the holomorphic obstruction map \( \Phi \) raises the question of whether there is a notion of holomorphic family of generalized complex structures. There is: if \( S \) is a complex manifold then a holomorphic family of generalized complex structures on \( M \) is a generalized complex structure on \( M \times S \) which can be pushed down, or reduced in the sense of \([3]\), via the projection to yield the complex structure on \( S \). The family \( \mathcal{M} \) can be shown to define such a holomorphic family, since the constructed family \( \epsilon(u) \) depends holomorphically on \( u \).

### 5.3 Examples of deformed structures

Consider deforming a compact complex manifold \((M, J)\) as a generalized complex manifold. Recall that the associated Lie algebroid is \( L = T_{0,1} + T_{1,0} \), so the deformation complex is simply the holomorphic multivector Dolbeault complex

\[
\big( \Omega^0 \cdot (\wedge_T T_{1,0}), \overline{\partial} \big).
\]

The base of the Kuranishi family therefore lies in the finite-dimensional vector space

\[
H^2(M, L) = \oplus_{p+q=2} H^q(M, \wedge^p T_{1,0}),
\]
whereas the image of the obstruction map lies in
\[ H^3(M, L) = \oplus_{p+q=3} H^q(M, \wedge^p T_{1,0}). \]

In this way, generalized complex manifolds provide a geometrical interpretation of the “extended complex deformation space” defined by Kontsevich and Barannikov [4]. Any deformation \( \epsilon \) has three components
\[ \beta \in H^0(M, \wedge^2 T_{1,0}), \quad \varphi \in H^1(M, T_{1,0}), \quad B \in H^2(M, \mathcal{O}). \]

The component \( \varphi \) is a usual deformation of the complex structure, as described by Kodaira and Spencer. The component \( B \) represents a residual action by cohomologically nontrivial \( B \)-field transforms; these do not affect the type. The component \( \beta \), however, is a new deformation for complex manifolds. Setting \( B = \varphi = 0 \), the integrability condition reduces to
\[ \partial \beta + \frac{1}{2} [\beta, \beta] = 0, \]
which is satisfied if and only if the bivector \( \beta \) is holomorphic and Poisson. Writing \( \beta = \frac{1}{4} (Q + iP) \) for \( Q, P \) real bivectors of type \((0,2) + (2,0)\) such that \( Q = PJ \), we may explicitly determine the deformed generalized complex structure:
\[ J_\beta = e^{\beta + \overline{\beta}} J e^{-(\beta + \overline{\beta})} = \begin{pmatrix} J & P \\ -J^* & -1 \end{pmatrix}. \]

In this way, we obtain a new class of generalized complex manifolds with type controlled by the rank of the holomorphic Poisson bivector \( \beta \).

**Example 5.6** (Deformed generalized complex structure on \( \mathbb{C}P^2 \)). For \( \mathbb{C}P^2, \wedge^2 T_{1,0} = \mathcal{O}(3) \), and for dimensional reasons, any holomorphic bivector \( \beta \in H^0(M, \mathcal{O}(3)) \) is automatically Poisson. Hence any holomorphic section of \( \mathcal{O}(3) \) defines an integrable deformation of the complex structure into a generalized complex structure. Since \( H^1(T_{1,0}) = H^2(\mathcal{O}) = 0 \), we may conclude from the arguments above that the locally complete family of deformations is smooth and of complex dimension 10. However one can also check that the obstruction space vanishes in this case, by the Bott formulae.

The holomorphic Poisson structure \( \beta \) has maximal rank outside its vanishing locus, which must be a cubic curve \( C \). Hence the deformed generalized complex structure is of \( B \)-symplectic type (type 0) outside \( C \) and of complex type (type 2) along the cubic. The complexified symplectic form \( B + i\omega = \beta^{-1} \) is singular along \( C \). We therefore have an example of a compact generalized complex manifold exhibiting type change along a codimension 2 subvariety.

**Example 5.7.** One can of course deform \( \mathbb{C}^2 \) in the same way that we have deformed \( \mathbb{C}P^2 \); we choose the holomorphic bivector
\[ \beta = z_1 \partial_{z_1} \wedge \partial_{z_2}, \]
where \( z_1, z_2 \) are the usual complex coordinates. Then applying a \( \beta \)-transform to the usual complex structure defined by the spinor \( \Omega = dz_1 \wedge dz_2 \), we obtain
\[ e^\beta \Omega = d\overline{z}_2 \wedge dz_2 + z_1, \]
which is precisely the example [4.8]. We see now that it is actually a deformation of the usual complex structure by a holomorphic Poisson structure.

Note that while holomorphic Poisson bivectors may be thought of as infinitesimal noncommutative deformations in the sense of quantization of Poisson structures, we are viewing them here as genuine (finite) deformations of the generalized complex structure. For more details about this distinction and its consequences, see [19], [16].
6 Generalized complex branes

In this section we introduce the natural “sub-objects” of generalized complex manifolds, generalizing both holomorphic submanifolds of a complex manifold and Lagrangian submanifolds in symplectic geometry. In fact, even in the case of a usual symplectic manifold, there are generalized complex branes besides the Lagrangian ones: we show these are the coisotropic A-branes discovered by Kapustin and Orlov [22].

As has been emphasized by physicists, a geometric description of a brane in \(M\) involves not only a submanifold \(\iota : S \rightarrow M\) but also a vector bundle supported on it; in cases where a nontrivial \(S^1\)-gerbe \(G\) is present one replaces the vector bundle by an object (“twisted vector bundle”) of the pullback gerbe \(\iota^* G\). Since the Courant bracket captures the differential geometry of the gerbe, we obtain a convenient description of branes in terms of generalized geometry. For simplicity we shall restrict our attention to branes supported on loci where the pullback gerbe \(\iota^* G\) is trivializable.

We begin by phrasing the definition of a gerbe trivialization in terms of the Courant bracket. Recall that \(\iota^* E\) denotes the pullback of exact Courant algebroids, defined in the Appendix.

**Definition 6.1.** Let \(E\) be an exact Courant algebroid on \(M\) and let \(\iota : S \rightarrow M\) be a submanifold. A (Courant) trivialization of \(E\) along \(S\) consists of a bracket-preserving isotropic splitting \(s : TS \rightarrow \iota^* E\) inducing an isomorphism

\[
s + \pi^* : (TS \oplus T^* S, [\cdot, \cdot]_0) \rightarrow \iota^* E.
\]

If an isotropic splitting \(\tilde{s} : TM \rightarrow E\) is chosen, with curvature \(H \in \Omega^3_c(M)\), then \(\iota^* E\) inherits a splitting with curvature \(\iota^* H\), and any trivialization \((\iota, s)\) is characterized by the difference \(s - \iota^* \tilde{s} = F \in \Omega^2(S)\), which satisfies

\[
\iota^* H = dF.
\]

(6.1)

Therefore the gerbe curvature is exact when pulled back to \(S\). Indeed, we obtain a generalized pullback morphism \(\rho \mapsto e^F \wedge \iota^* \rho\), defining a map from the twisted de Rham complex of \(M\) to the usual de Rham complex of \(S\):

\[
(\Omega^*(M), d_H) \xrightarrow{e^F, \iota^*} (\Omega^*(S), d).
\]

This may be viewed as the the image under the Chern character of a morphism from the twisted K-theory of \(M\) to the usual K-theory of \(S\).

To avoid confusion, let \(E|_S\) denote the restriction of the bundle \(E\) to \(S\), as opposed to \(\iota^* E = K^\perp / K\), for \(K = \text{Ann}(TS)\), which defines the pullback Courant algebroid over \(S\). The trivialization \((\iota, s)\) defines a maximal isotropic subbundle \(s(TS) \subset \iota^* E\). Further, the quotient map \(q : K^\perp \rightarrow K^\perp / K\) determines a bijection taking maximal isotropic subbundles \(L \subset \iota^* E\) to maximal isotropic subbundles \(q^{-1}(L) \subset E|_S\) contained in \(K^\perp\).

**Definition 6.2.** The generalized tangent bundle to the trivialization \(\mathcal{L} = (\iota, s)\) of \(E\) is the maximal isotropic subbundle \(\tau_{\mathcal{L}} \subset E|_S\) defined by \(\tau_{\mathcal{L}} = q^{-1}(s(TS))\).

Note that \(\text{Ann}(TS) = N^* S\), so that \(\tau_{\mathcal{L}}\) is actually an extension of the tangent bundle by the conormal bundle:

\[
0 \longrightarrow N^* S \longrightarrow \tau_{\mathcal{L}} \longrightarrow TS \longrightarrow 0.
\]

(6.2)

If a splitting \(\tilde{s} : TM \rightarrow E\) is chosen, with \(s - \iota^* \tilde{s} = F \in \Omega^2(S)\) as in (6.1), then \(\tau_{\mathcal{L}}\) has the explicit form

\[
\tau_{\mathcal{L}} = \{X + \eta \in TS \oplus T^* M : \iota^* \eta = i_X F\}.
\]

(6.3)
Comparing this with Proposition 2.10, we obtain the following canonical example of a Courant trivialization:

**Example 6.3.** Let $L \subset (TM \oplus T^*M, [\cdot,\cdot]_H)$ be a Dirac structure and let $\iota : S \hookrightarrow M$ be a maximal integral submanifold for the (generalized) distribution $\Delta = \pi(L) \subset TM$. Then along $S$, we have $L = L(\Delta, \varepsilon)$ for a unique $\varepsilon \in \Omega^2(S)$, and by the same argument as in Proposition 2.10 we obtain

$$\iota^* H = d\varepsilon.$$ 

Therefore we see that a Dirac structure induces a (generalized) foliation of the manifold by trivializations $\mathcal{L} = (\iota, \varepsilon)$.

Note that in this example, $\tau_L = L|_S$ inherits a Lie algebroid structure over $S$, since any sections $u, v \in C^\infty(S, \tau_L)$ may be extended to $\tilde{u}, \tilde{v} \in C^\infty(M, L)$ and then the expression

$$[u, v] := [\tilde{u}, \tilde{v}]|_S$$

is independent of extension and defines a Lie bracket. For general trivializations, however, the ambient Dirac structure $L$ is unavailable, and the argument fails.

A complex submanifold $S \subset M$ of a complex manifold is defined by the property that $J(TS) = TS$. Similarly, we define a compatibility condition between a Courant trivialization and a generalized complex structure.

**Definition 6.4.** A Courant trivialization $\mathcal{L} = (\iota, s)$ is said to be compatible with the generalized complex structure $\mathcal{J}$ if and only if

$$\mathcal{J}(\tau_L) = \tau_L,$$

i.e. its generalized tangent bundle is a complex subbundle of $E$.

An immediate consequence of the definition is that $\pi(\mathcal{J}(N^*S)) \subset TS$, which by Proposition 3.24 is the statement that $P(N^*S) \subset TS$, i.e. $S$ is a coisotropic submanifold for the Poisson structure $P$. Since $P$ is Poisson, $\Delta = P(N^*S)$ integrates to a singular foliation called the characteristic foliation of $S$.

Decomposing $\tau_L \otimes \mathbb{C}$ into $\pm i$-eigenspaces for $\mathcal{J}$, we obtain

$$\tau_L \otimes \mathbb{C} = \ell \oplus \bar{\ell}$$

Note that the isotropic subbundle $\ell \subset (E \otimes \mathbb{C})|_S$ is contained in the ambient $+i$-eigenbundle $L$ of $\mathcal{J}$, i.e.

$$\ell \subset L|_S.$$ 

Therefore, the argument of Example 6.3 concerning restriction of Courant brackets applies and we obtain the following result.\footnote{This Lie algebroid was obtained independently by Kapustin and Li [21], as defining the BRST complex describing open strings with both ends on $\mathcal{L}$.}

**Proposition 6.5.** Let $\mathcal{J}$ be a generalized complex structure and let $\mathcal{L}$ be a compatible Courant trivialization. Define $\ell = \ker((\mathcal{J} - i)\cap (\tau_L \otimes \mathbb{C})$. Then the Courant bracket induces a Lie bracket on $C^\infty(S, \ell)$, making $(\ell, [\cdot,\cdot], \pi)$ into a complex Lie algebroid over $S$.

The associated Lie algebroid complex $(C^\infty(S, \Lambda^\bullet \ell^*), d_\ell)$ is actually elliptic, by the same reasoning as in Proposition 3.13, and may be used to study the deformation theory of $\mathcal{L}$, which we leave for a future work.

The Lie algebroid $\ell$ projects to a generalized distribution $A = \pi(\ell) \subset TS \otimes \mathbb{C}$, which is integrable and satisfies $A + \bar{A} = TS \otimes \mathbb{C}$. The intersection $A \cap \bar{A} = \Delta \otimes \mathbb{C}$ coincides with the characteristic distribution of the coisotropic submanifold $S$. Therefore, by the reasoning in Proposition 1.2 wherever $\Delta$ has constant rank, $A$ defines an invariant integrable holomorphic structure transverse to the characteristic foliation.
Corollary 6.6. Let $\mathcal{L}$ be a compatible trivialization and let $\ell$ be the complex Lie algebroid defined above. In a neighbourhood where the characteristic distribution is of constant rank, $A = \pi(\ell) \subset TS \otimes \mathbb{C}$ defines an integrable holomorphic structure transverse to the characteristic foliation, which descends to the leaf space.

Since $\ell$ is a Lie algebroid, we may associate to any compatible trivialization $\mathcal{L}$ the category of $\ell$-modules, i.e. complex vector bundles $V$ over $S$, equipped with flat Lie algebroid connections with respect to $\ell$. We call these generalized complex branes on $\mathcal{L}$.

Definition 6.7 (Generalized complex brane). Let $\mathcal{J}$ be a generalized complex structure and $\mathcal{L}$ a compatible trivialization. A generalized complex brane supported on $\mathcal{L}$ is a module over the Lie algebroid $\ell$.

We now indicate that there is a natural pullback map taking generalized holomorphic bundles ($L$-modules) over $M$ to $\ell$-modules over $S$. As a result, any compatible Courant trivialization immediately supports not only the trivial brane $V = \mathbb{C} \times S$ but also the canonical brane $\iota^*K$, where $K$ is the canonical line bundle.

Proposition 6.8. Let $\mathcal{L} = (\iota, s)$ be a compatible trivialization and $V$ a generalized holomorphic bundle over $M$. Then $\iota^*V$ is naturally a $\ell$-module, and hence a generalized complex brane.

Proof. Let $j : \ell \hookrightarrow L |_S$ denote the inclusion, and let $\mathcal{J} : C^\infty(V) \longrightarrow C^\infty(L^* \otimes V)$ be the flat Lie algebroid connection defining the $L$-module structure. Then for $v \in C^\infty(S, \iota^*V)$, choose an extension $\tilde{v} \in C^\infty(M, V)$ and define $D : C^\infty(S, \iota^*V) \longrightarrow C^\infty(S, \iota^* \otimes \iota^*V)$ by

$$Dv := j^*(\mathcal{J}\tilde{v})|_S.$$

This is independent of extension since $\pi(\ell) \subset TS \otimes \mathbb{C}$, and is easily seen to be a flat $\ell$-connection. \qed

We now describe the detailed structure of generalized complex branes in the extremal cases of complex and symplectic geometry.

Example 6.9 (Complex branes). Let $\mathcal{L} = (\iota, F)$, for $\iota : S \hookrightarrow M$ and $F \in \Omega^2(S)$, be a generalized complex trivialization in a complex manifold, so that $\iota^*H = dF$ and $\tau_\mathcal{L}$, given by (6.3), is a complex subbundle for $\mathcal{J}_J = \begin{pmatrix} -J & J^* \end{pmatrix}$.

This happens if and only if

- $TS \subset TM$ is a complex subbundle for $J$, i.e. $S$ is a complex submanifold, and
- $J^*i_X F + i_{JX} F \in N^* S$ for all $X \in TS$, i.e. $F$ is of type $(1,1)$.

In this case, the Lie algebroid $\ell$ is given by

$$\ell = \{ X + \xi \in T_{0,1} S \oplus T_{1,0}^* M : \iota^* \xi = i_X F \},$$

and is therefore isomorphic to $T_{0,1} S \oplus N^*_{1,0} S$, where $N^*_{1,0} S$ denotes the holomorphic conormal bundle of $S$. As a result, a generalized complex brane supported on $\mathcal{L}$ consists of a holomorphic vector bundle $V$ over $S$, together with a holomorphic section $\phi : V \longrightarrow N^*_{1,0} S \otimes V$ satisfying $\phi \wedge \phi = 0 \in \wedge^2 N^*_{1,0} S \otimes \text{End}(V)$.

One sees directly from the description in Example 3.19 of generalized holomorphic bundles that $\ell$-modules may be obtained by pullback of $L$-modules.
Example 6.10 (Symplectic branes). As in the previous example, let $\mathcal{L} = (\iota, F)$ be a compatible trivialization, but for a symplectic structure $J = -\omega^{-1}$. If $F = 0$, then $\tau_L = TS \oplus N^* S$, and $J(\tau_L) = \tau_L$ is simply the requirement that $\omega^{-1}(N^* S) \subset TS$ and $\omega(TS) \subset N^* S$, i.e. $S$ is a Lagrangian submanifold. In this particular case, $\ell = \{X - i\omega(X) : X \in TS\}$, so that $\ell$ is isomorphic as a Lie algebroid to $TS$ itself; hence $\ell$-modules are simply flat vector bundles supported on $S$.

However, there are symplectic branes beyond the flat bundles over Lagrangians if we allow $F \neq 0$; in general, as we saw in Corollary 6.6, $S$ must be coisotropic and the Lie algebroid $\ell$ determines a complex distribution $A = \pi(\ell)$ defining an invariant holomorphic structure transverse to the characteristic foliation of $S$. However for a symplectic trivialization we have explicitly $\ell = (\tau_L \otimes \mathbb{C}) \cap \Gamma_{-i\omega}$, and hence

$$\ell = \{X - i\omega(X) \in (TS \oplus T^* M) \otimes \mathbb{C} : iX(F + i\omega) = 0\}. \tag{6.4}$$

Since $A = \pi(\ell)$ and $\Delta \otimes \mathbb{C} = A \cap \overline{A}$ defines the characteristic foliation, (6.4) implies that $F + i\omega$ is basic with respect to the foliation and defines a closed, nondegenerate $(0, 2)$-form on the leaf space. Hence the leaf space inherits a natural holomorphic symplectic structure. In this way we obtain precisely the structure of coisotropic $A$-brane, discovered by Kapustin and Orlov [22] in their search for geometric objects of the Fukaya category beyond the well-known Lagrangian ones.

For such coisotropic trivializations, $\ell$ is isomorphic as a Lie algebroid to the distribution $A = \pi(\ell)$, and so branes are vector bundles equipped with flat partial $A$-connections. This implies that they are flat along the characteristic distribution, transversally holomorphic and invariant along the distribution. Holomorphic bundles pulled back from the leaf space would provide examples.

Example 6.11 (Space-filling symplectic brane). A special case of the preceding example is when the submanifold $S$ coincides with $M$ itself; then any brane over $\mathcal{L} = (\text{id}, s)$ is said to be space-filling. By the preceding argument, $\mathcal{L}$ may be described by a closed 2-form $F \in \Omega^2(M)$ such that

$$\sigma = F + i\omega$$

defines a holomorphic symplectic structure on $M$, with complex structure given by $J = -\omega^{-1} F$.

If $M$ supports such a space-filling brane, then any complex submanifold $\iota : S \hookrightarrow M$ which is also coisotropic with respect to $\sigma$ (for example, a complex hypersurface) defines a compatible trivialization $\mathcal{L}' = (\iota, \iota^* F)$ in $M$, and we may produce examples of branes on $\mathcal{L}'$ by pullback. The holomorphic symplectic structure on its leaf space is also known as the holomorphic symplectic reduction of $\mathcal{L}'$.

Example 6.12 (General space-filling branes). The existence of a space-filling generalized complex brane places a strong constraint on the generalized complex structure. Indeed, the generalized tangent bundle $\tau_L$ determines an integrable isotropic splitting of the Courant algebroid

$$E = T^* \oplus \tau_L,$$

so that the curvature $H$ vanishes. If $\mathcal{J}$ is the generalized complex structure, the constraint $\mathcal{J}(\tau_L) = \tau_L$ implies that $\mathcal{J}$ must have upper triangular form in this splitting:

$$\mathcal{J} = \begin{pmatrix} -J & P \\ J^* & \end{pmatrix}. \tag{6.4}$$
Here we use the canonical identification \( \tau_C = TM \). Since \( \mathcal{J} \) is upper triangular, \( J \) is an integrable complex structure, for which \( T_{0,1} = \ell \). The real Poisson structure \( P \) is of type \((2,0) + (0,2)\) as can be seen from the fact \( JP = PJ^* \), and the complex bivector \( \beta = \frac{1}{\ell}(Q + iP) \), for \( Q = PJ^* \), is such that the \(+i\)-eigenbundle of \( \mathcal{J} \) can be written as

\[
L = T_{0,1} \oplus \Gamma_\beta,
\]

where \( \beta \) is viewed as a map \( T_{1,0} \to T_{1,0} \). Courant integrability then requires that \( \beta \) be a holomorphic Poisson structure. Therefore we see that space-filling branes only exist when \( \mathcal{J} \) is a holomorphic Poisson deformation of a complex manifold.

In fact, one can show using a combination of the above arguments, or as is done in [39] by developing a theory of brane reduction, that for an arbitrary generalized complex brane, the Poisson and holomorphic structures transverse to the characteristic foliation (when it is regular) are compatible, defining an invariant transverse holomorphic Poisson structure.

Interesting relations between the coisotropic branes discussed in this section and noncommutative geometry have appeared in [20], in particular; for more on this connection as well as the relation between coisotropic branes and generalized Kähler geometry, see [10].

7 Appendix

**Proposition 7.1.** Let \( E \) be an exact Courant algebroid over \( M \) with Ševera class \([H]\), and suppose \( \iota : S \hookrightarrow M \) is a submanifold. Then

\[
\iota^*E := K^\perp/K,
\]

for \( K = \text{Ann}(TS) \subset E|_S \), inherits the structure of an exact Courant algebroid over \( S \) with Ševera class \( \iota^*[H] \).

**Proof.** We first show that \( \iota^*E \) inherits a bracket. Let \( u, v \in C^\infty(S, K^\perp/K) \), and choose representatives \( u', v' \in C^\infty(S, K^\perp) \). Extend these over \( M \) as sections \( \tilde{u}, \tilde{v} \in C^\infty(M, E) \). We claim that \([\tilde{u}, \tilde{v}]|_S \) defines a section of \( \iota^*E \) which is independent of the choices made.

Firstly we observe that \([\tilde{u}, \tilde{v}]|_S \in C^\infty(S, K^\perp) \), since \( \pi[\tilde{u}, \tilde{v}] = [\tilde{\pi} \tilde{u}, \tilde{\pi} \tilde{v}] \) and if \( X, Y \) are vector fields tangent to \( S \) then \([X, Y]\) is also tangent to \( S \).

Secondly we claim that \([\tilde{u}, \tilde{v}] + K \) is independent of the choices made: for \( p, q \in C^\infty(E) \) with \( p|_S, q|_S \in C^\infty(S, K) \), we have

\[
[\tilde{u} + p, \tilde{v} + q] - [\tilde{u}, \tilde{v}] = [\tilde{u}, q] + [p, \tilde{v}] + [p, q].
\]

Given any \( x \in C^\infty(E) \) with \( \pi(x)|_S \in C^\infty(S, TS) \), we verify that \( \langle x, [\tilde{u}, q] \rangle = \pi(\tilde{u})\langle x, q \rangle - \langle [\tilde{u}, x], q \rangle \) vanishes upon restriction to \( S \), since \( \langle x, q \rangle \) vanishes along \( S \) and \( \pi([\tilde{u}, x]) \) is tangent to \( S \). Similarly for the other two terms. This shows that \([\tilde{u}, \tilde{v}] + K \) is independent of the choices made. The remainder of the Courant algebroid properties are easily verified. \[\square\]

**Proposition 7.2.** Let \( L \subset E \) be a Dirac structure and assume that

\[
\iota^*L := \frac{L \cap K^\perp + K}{K}
\]

is a smooth subbundle of \( \iota^*E \). Then it is a Dirac structure.

**Proof.** We need only verify that the maximal isotropic subbundle \( \iota^*L \) is involutive. Let \( u, v \in C^\infty(S, (L \cap K^\perp + K)/K) \). By the definition of the Courant bracket in Proposition 7.1 we may choose representatives \( u', v' \in C^\infty(S, L \cap K^\perp + K) \) for \( u, v \) and extend these as sections
of \( E \) over \( M \) in any way. In a neighbourhood \( U \subset S \) where \( L \cap K^\perp \) has constant rank, write \( u' = x' + p', \; v' = y' + q' \), where \( x', y' \in C^\infty(U, L \cap K^\perp) \) and \( p', q' \in C^\infty(U, K) \). Then choose extensions \( x, y \in C^\infty(V, L) \) for \( x', y' \) and \( p, q \in C^\infty(V, E) \) for \( p', q' \), where \( V \) is an open set in \( M \) containing \( U \). Then

\[
[x + p, y + q] = [x, y] + [x, q] + [p, y] + [p, q].
\]

Since \( x, y \in C^\infty(V, L) \) and \( \pi(x), \pi(y) \) are tangent to \( S \), \( [x, y]|_S \in C^\infty(U, L \cap K^\perp) \). Also, \( [x, q]|_S \in C^\infty(U, K) \) since, for \( z \in C^\infty(V, E) \) with \( \pi(z) \) tangent to \( S \),

\[
\langle z, [x, q] \rangle = \pi(x)\langle z, q \rangle - \langle [x, z], q \rangle,
\]

which vanishes along \( S \) since \( z \) and \( [x, z] \) are both tangent to \( S \). The same argument applies to show \( [p, y]|_S, [p, q]|_S \in C^\infty(S, K) \). This proves that \( [x + p, y + q]|_S \in C^\infty(S, L \cap K^\perp + K) \), and hence that \( \iota^*L \) is involutive in \( U \). Since \( L \cap K^\perp \) has locally constant rank on an open dense set in \( S \), this argument shows that \( \iota^*L \) is involutive, as required.

\[ \square \]
